Arbitrage and Market Frictions

<div style="text-align:right">**32**</div>

Shashidhar Murthy

Abstract

Arbitrage is central to finance. The classical implications of the absence of arbitrage are derived in economies with no market frictions. A recent literature addresses the implications of no-arbitrage in settings with various market frictions. Examples of the latter include restrictions on short sales, different types of impediments to borrowing, and transactions costs. Much of this literature employs assumptions of continuous time and a continuous state space. This selected review of the literature on arbitrage and market frictions adopts a framework with discrete states. It illustrates and discusses a sample of the principal results previously obtained in continuous frameworks, clarifying the underlying intuition and enabling their accessibility to a wider audience.

32.1 Introduction

The concept of arbitrage and the requirement that there be no arbitrage opportunities is central to finance. Essentially, an arbitrage opportunity is an investment where one can get something for nothing: a trading strategy with zero or negative current cost that is likely to yield a positive return and sure to not entail a future liability. Thus, the requirement that there be no arbitrage is a minimal desired attribute of a properly functioning securities market.

The implications of the absence of arbitrage are central to much of finance, simultaneously illuminating many areas and giving rise to new fields of inquiry. From early developments of the spot-forward parity relationships to the fundamental irrelevance propositions of Modigliani and Miller (1958), many arguments have at least implicitly used the main intuition of no-arbitrage that close substitutes must obey the law of one price, viz. two securities with the same payoffs must have the same price. Modern day application of this intuition came to the fore with the Black and Scholes (1973) model of option pricing. A first systematic analysis of the implications of no arbitrage was then carried out by Ross (1976, 1978). The principal question in such analysis is: given a set of some primitive assets, how much can one infer about the valuation of other assets if there are to be no arbitrage opportunities? Both the analysis of Ross (1976, 1978) and its generalization by Harrison and Kreps (1979) assume that investors are able to trade in frictionless markets.

A recent, burgeoning literature addresses the implications of no-arbitrage in settings with various market frictions. Examples of the latter include restrictions on short sales, different types of impediments to borrowing, and transactions costs. This paper reviews a selected portion of this literature and surveys the principal results obtained. Much of this literature employs the assumption of continuous time or an infinite dimensional state space. Here, a discrete framework is adopted in the interest of clarifying

the intuition behind previously obtained results and rendering them accessible to a wider audience.

The principal implication of no-arbitrage in a frictionless setting may be summarized by what is sometimes known as the Fundamental Theorem of Asset Pricing (Dybvig and Ross, 1987). This theorem states that the absence of arbitrage is equivalent to the existence of both a strictly positive linear pricing rule and a solution to the choice problem of some investor who prefers more to less. Apart from implying that the law of one price holds, this result has several alternative representations and implications. One of the best known is that the no-arbitrage value of a claim is the cost of a portfolio that exactly replicates or hedges the claim's payoff. A second is that relative prices of assets must be martingales under a "risk neutral" probability measure.

Rather than purport to be an exhaustive survey, this paper reviews a sample of the main results from the literature on arbitrage and market frictions.[1] One striking result is that the cheapest way to hedge a given liability may be to hedge a larger liability. This was first shown by Bensaid et al. (1992) in a transactions costs setting. An implication of this is that pricing may fail to be linear and instead be sublinear: the value of the sum of payoffs may be less than the sum of the values of the individual payoffs. Thus, there may be room for financial innovation, or departures from Modigliani–Miller (1958) type irrelevance, where an intermediary pools securities, and then strips them; see Chen (1995) for a discussion. When there are no frictions, the price paid when buying a claim is also the amount received in going short or writing the claim. Market frictions which result in sublinearity of the valuation or pricing rule can lead to bid–ask spreads on derivative securities even when there are no transactions costs (i.e. bid–ask spreads) in trading the primary securities, as shown by Luttmer (1996).

Furthermore, departures from the law of one price and the martingale property may occur under frictions. In the presence of a short sales constraint that changes elastically depending on the collateral posted. Hindy (1995) showed that an asset's value depends not only on its dividends but also on the collateral services it provides. When investors face short sales or borrowing constraints, Jouini and Kallal (1995a, b) show that asset prices may be super martingales.

The rest of this paper is organized as follows. A basic framework is set out in the next section, following which the benchmark case of no frictions is discussed in Section 32.3. Due to limitations of space, we formally illustrate the above results considering primarily the case of no short sales in Sections 32.4 and 32.5. However, we also briefly outline the impact of other types of frictions such as constraints on portfolio weights that permit some short sales (such as that under a leverage constraint or margin restriction), and transactions costs in Section 32.6. We conclude with some remarks relating to the consistency with equilibrium of results obtained from the no-arbitrage approach under frictions.

32.2   A Basic Framework

Consider an economy over dates $t = 0$ and T. Uncertainty is described by a discrete state space Ω with typical member ω $\{1,\ldots,N\}$ denoting the final state of nature realized at date T where $N < \infty$. The probabilities of these states are $\{p(\omega)\}$ corresponding to an underlying probability measure P.

Investors trade a set of primitive assets which are in positive net supply, and whose prices are taken as given. Asset $j = 1,\ldots, J$ has price $S_j(0)$ at date 0 and the future price $S_j(\omega)$ $\equiv D_j(\omega)$ in state ω at date T, where D_j is a given random dividend or payoff. Asset $j = 1$ is taken to be a risk-free bond with current price of unity; (one plus) its constant interest rate is denoted R. A portfolio choice is $z \equiv (z_1,\ldots,z_J)$, comprising holdings of shares of the various assets at date 0. Investors choose portfolios to maximize their preferences that are strictly increasing in consumption at dates 0 and T.

Trading in assets is subject to market frictions that take the form of a constraint on short sales and/or borrowing. The formulation we will consider for most of this paper restricts holdings of shares of some or all assets to be at least as large as exogenously given lower bounds: $z_j \geq -\underline{z}_j$, where $\underline{z}_j \geq 0$.[2] In the case of no short sales of asset j, $\underline{z}_j = 0$; if instead some limited but fixed amount of short sales is permitted, $\underline{z}_j > 0$. Similarly, note that the no borrowing case corresponds to $\underline{z}_1 = 0$, since asset $j = 1$ is the risk-free bond. A portfolio that satisfies the short sales constraint is termed admissible.

Investors can use the primitive assets to create, i.e. exactly replicate, various payoffs using admissible portfolios. Every such payoff $x \equiv \{x(\omega)\}$, where $x(\omega) = \sum z_j S_j(\omega)$ is hence said to be marketed, i.e. available for purchase and/or sale. In the presence of market frictions, the set of marketed payoffs is not limited to those payoffs that can be explicitly replicated. For instance, consider a payoff x of 1 in some state ω' and 0 in other states whose replication require a portfolio that involves a short position in asset j (and positions in other securities). Suppose, the latter short position is equal to the maximum amount permitted of $\underline{z}_j > 0$. Then, the payoff $2x$ cannot be exactly replicated because it would require a short position of $2\underline{z}_j$ shares. However, the payoff $2x$ may still be termed marketed if there exists a portfolio that produces *at least* 2 in state ω' and 0 elsewhere; i.e. if the payoff can be *super-replicated*.

Thus, it is natural to define a price for an arbitrary payoff x as the minimum cost

$$\phi(x) \equiv \left\{ \sum_j z_j S_j(0) : x(\omega) \leq \sum_j z_j S_j(\omega), \forall \omega \right\} \quad (32.1)$$

at which it can be exactly replicated or super-replicated by an admissible portfolio, where the associated functional $\phi(.)$ is termed a pricing or valuation rule.[3]

An arbitrage opportunity is an admissible portfolio z that either has (1) a nonpositive cost $\sum z_j S_j(0)$ when initiated and a date T payoff $x \equiv \{x(\omega)\}$, where $x(\omega) = \sum z_j S_j(\omega)$, which is positive in some states and nonnegative in others, or (2) a negative current cost and a nonnegative future payoff in all states.

32.3 Exact Replication and Prices Under No Frictions

At this stage, it is useful to present the principal result on the implications of the absence of arbitrage for the benchmark case where there are no market frictions. This result, known as the Fundamental Theorem of Asset Pricing, is due to Ross (1976, 1978). Given the definition of the pricing or valuation operator ϕ (.), it is clear that there are no arbitrage opportunities in this frictionless setting only if every non-negative marketed payoff x (which is also positive in some state) has price ϕ $(x) > 0$. The result below establishes a further property: that of linearity. See Dybvig and Ross (1987) for a proof of the result below.

Proposition 1 *Suppose there are no market frictions, i.e. $z_j = \infty, \forall j$. Then there are no arbitrage opportunities if and only if the pricing rule in Equation 32.1, denoted $\phi^*(.)$ here, is positive and linear.*

Apart from implying that the law of one price must hold, the linearity property means that $\phi^*(\lambda x) = \lambda \phi^*(x)$ for all λ, i.e. the price functional is homogeneous. It is useful to further interpret the above result in terms of an implicit state price vector $\xi \equiv \{\xi(\omega)\}$, where $\xi(\omega)$ is the price of a state security that pays 1 unit in state ω, and 0 elsewhere. The linearity and positivity of $\phi^*(.)$ are equivalent to $\phi^*(x) = \sum_\omega \xi(\omega) x(\omega)$ and $\xi(\omega) > 0$, respectively. The pricing rule $\phi^*(.)$ values every marketed payoff precisely because the latter can be exactly replicated, or hedged, using a portfolio of existing assets: it assigns a value equal to the cost of the replicating portfolio.

Another useful interpretation of the linearity of $\phi^*(.)$ is that there exists a ("risk-neutral") probability measure Q^* that is equivalent to the underlying measure P under which relative or normalized asset prices are martingales. Thus, every primitive asset's current price relative to, say, the price of the bond (which is 1), is equal to the expectation under Q^* of its future payoffs relative to that of the bond: $S_j(0) = E^{Q^*}[D_j R^{-1}]$. Equivalently, the value of every payoff satisfies $\phi(x) = \sum_\omega q^*(\omega) x(\omega) R^{-1}$, where $q^*(\omega)$ denotes the risk-neutral probability of state ω under Q^*. These well known implications of no-arbitrage in frictionless markets provide the basis of most option pricing models, following Black and Scholes (1973), Merton (1973), and Cox and Ross (1976).

32.4 No Short Sales

We now return to the economy with frictions of Section 32.2, and consider the case of no short sales. As in the frictionless case, it is clear that there are no arbitrage opportunities in this setting only if every nonnegative marketed payoff x (which is positive in some state) has price ϕ $(x) > 0$. We proceed by recording a result below that is the counterpart to Proposition 1.

Proposition 2 *Suppose the only friction is that the short sales of some assets is prohibited, i.e. $z_j = 0$ for some j, and $z_j = \infty$ for the rest. Then there are no arbitrage opportunities if and only if the pricing rule in Equation 32.1, denoted $\phi^{NS}(.)$ here, is positive and sublinear. Furthermore, there exist underlying positive hypothetical linear pricing rules ϕ (.) such that $\phi^{NS}(x) \geq \phi$ (x), for all marketed payoffs x. Also, there exists a new probability measure associated with $\phi^{NS}(.)$ under which the (normalized) price process of an asset is a super martingale if the asset cannot be sold short, and a martingale if the asset can be sold short.*[4]

The proof follows from Garman and Ohlson (1981), Chen (1995), Jouini and Kallal (1995a, b), and Luttmer (1996) and rather than reproduce it here, we will shortly present a simple binomial example where the result is explicitly illustrated. (Also note that while some of these papers consider transactions costs, their results apply here). But first, a few implications of the sublinearity property and the supermartingale property are discussed.

Observe that, in contrast to Proposition 1, the pricing rule $\phi^{NS}(.)$ is not linear but sublinear. The sublinearity implies that the value of a portfolio of two payoffs x and y may be less than the sum of the values of the payoffs, i.e. $\phi^{NS}(x + y) \leq \phi^{NS}(x) + \phi^{NS}(y)$.

It also implies that $\phi^{NS}(\lambda x) = \lambda \phi^{NS}(x)$ for all $\lambda \geq 0$, i.e. the price functional is positively homogeneous.

Chen (1995) discusses the role of financial innovation in such a context. He shows that an innovator (who is assumed to not face any short sales constraint, unlike other investors) can earn profits by purchasing a "pooled" payoff $x + y$ at a cost $\phi^{NS}(x + y)$, stripping it into individual components x and y, and selling (i.e. issuing) the latter at prices $\phi^{NS}(x)$ and $\phi^{NS}(y)$, respectively. Other investors cannot earn the same profits because they cannot short-sell (i.e. issue) the individual component securities x and y. In a frictionless economy, in contrast, the linearity of the pricing rule $\phi^*(.)$ leaves no role for such financial innovation; i.e. the Modigliani–Miller (1958) invariance proposition holds.

Next, consider the relationship between the value of a security with payoff x and another security with payoff $- x$. In a frictionless world, the values of these two securities (the

second security is essentially equivalent to going short the first) are the negative of each other, i.e. their values sum to 0. This follows from the linearity (homogeneity) of the valuation rule ϕ^*. Under no short sales, the valuation rule $\phi^{NS}(.)$ is only positively homogeneous, and thus $\phi^{NS}(-x)$ may differ from $-\phi^{NS}(x)$. The intuition is just that the cost of super-replicating a payoff x will in general differ from that for the payoff $-x$. Also note that since the value of a zero payoff must be zero, $\phi^{NS}(x) + \phi^{NS}(-x)$ is at least as large as $\phi^{NS}(x + (-x)) = \phi^{NS}(0) = 0$; i.e. the sum of the values of both securities may be positive. Consequently, the ask price $\phi^{NS}(x)$ of the payoff x may exceed the bid price $-\phi^{NS}(-x)$. Thus, as Jouini and Kallal (1995a, b) and Luttmer (1996) show, a derivative security's price may exhibit a bid–ask spread even where there are no transactions costs (i.e. bid–ask spreads) in trading the primitive assets.

As we noted in Section 32.3, asset prices (normalized by, say, the bond) in frictionless economies are martingales under the risk-neutral probability measure. In other words, one cannot expect to earn more than the risk-free rate after correcting for risk. In sharp contrast, Proposition 2 shows that there exists a risk-neutral probability measure, say Q^{NS}, under which (normalized) prices of assets subject to short sales constraints are super martingales. In other words, $S_j(0)/R^{-1} \geq E^{QNS}[D_j]$ for such assets: their prices after correcting for risk and the risk-free return are expected to be nonincreasing. This is compatible with the absence of arbitrage opportunities from the perspective of a risk-neutral investor because an asset whose price is expected to decrease relative to the bond cannot be sold short. This super martingale property was proved by Jouini and Kallal (1995a, b) in a model with short sales constraints (and transactions costs).

32.5   A Simple Binomial Model

As an example of a simple model that explicitly illustrates the results of Proposition 2 and their significance, we now consider a one-period binomial model. A stock and bond are traded with the constraint that no short sales of the stock is permitted, but borrowing (short sales of the bond) is allowed. The stock's current price is S and its end-of-period price is uS in state u, and dS in state d. The bond has current price of unity and one plus a risk-less return of R where $d < R < u$.

Consider a payoff $x \equiv (x_d, x_u)$ comprised of x_d in state d and x_u in state u. Hedging any such payoff requires a portfolio of z_s shares of the stock and z_b units of the bond that satisfies

$$z_s \omega S + z_b R \geq x_\omega \ \text{ and } \ z_s \geq 0, \qquad (32.2)$$

where ω {d, u} denotes both the future state and the return of the stock. Note from Equation 32.2 we allow for the possible super-replication of the payoff; also observe that

z_s must satisfy the no-short-sales constraint. Since the cost of the hedge portfolio is $z_s S + z_b$ it follows, using Equations 32.1 and 32.2, that the value of the payoff is

$$\phi^{NS}(x) \equiv Min \ \{z_s S + z_b : z_s \omega S + z_b R \geq x_\omega;$$
$$z_S \geq 0;$$
$$\omega \in \{d, u\}\}, \qquad (32.3)$$

i.e. it equals the cost of the cheapest hedge portfolio.

Denote the risk-neutral probability of state u in the frictionless counterpart to the above example by $q^* \equiv (R - d)/(u - d)$. It is then easy to verify that the solution to Equation 32.3 is:

$$\phi^{NS}(x) = [q^* x_u + (1 - q^*) x_d] R^{-1} \text{ if } x_u \geq x_d \qquad (32.4)$$

and

$$\phi^{NS}(x) = x_d R^{-1} \text{ if } x_u < x_d. \qquad (32.5)$$

In other words, for a payoff such as that of a call option, where $x_u > x_d$, the value is given by Equation 32.4 and is no different from what it would be in a frictionless world. This is because exact replication, or an exact hedge, of the call entails a long position in the stock and borrowing. In contrast, for a security such as a put option, where $x_u < x_d$, the value in Equation 32.5 is just the discounted value of the payoff in the "down" state discounted at the risk-free return. The reason is that an exact hedge or replication of the put would require short sales of the stock and is hence infeasible due to the no-short-sales constraint. Instead, the cheapest super-replication of the put involves a long bond position with face value x_d.

To see that the valuation functional ϕ^{NS} in Equations 32.4 and 32.5 is sublinear, compare the value of the payoff (dS, uS) from the stock with the sum of the values $\phi^{NS}(dS, 0)$ and $\phi^{NS}(0, uS)$. The former is obviously $\phi^{NS}(dS, uS) = [q^* uS + (1 - q^*) dS] R^{-1} = S$. However, the latter sum, $\phi^{NS}(dS, 0) + \phi^{NS}(0, uS) = dSR^{-1} + [q^* uS + (1 - q^*) 0] R^{-1} = S + dSR^{-1} q^*$, exceeds the current stock price, and this proves the sub-linearity. The intuition is that the cost of hedging the combined payoff (dS, uS) is less than the sum of the costs of hedging $(dS, 0)$ and $(0, uS)$ because hedging $(dS, 0)$ entails super-replication.

Finally, we show how the super martingale property of Proposition 2 comes about. Recall that with no frictions, $q^* \equiv (R - d)/(u - d)$ is the risk-neutral probability of state u under which the stock, bond, and all other payoffs (i.e. options) are martingales. Now define the probability q [$0, q^*$] and the associated hypothetical linear valuation rule $\phi^q(x) = [q x_u + (1 - q) x_d] R^{-1}$. It is easy to verify that the actual sublinear valuation rule $\phi^{NS}(.)$ of the economy with

short sales constraints in Equations 32.4 and 32.5 is related to the sets $\{q\}$ and $\{\phi^q(.)\}$ by:

$$\phi^{NS}(x) = \text{Max} \{\phi^q(x) : q \in [0, q^*]\}. \qquad (32.6)$$

Compared to the probability q^*, every other probability q $[0, q^*]$ places less weight on the "up" state and more weight on the "down" state. Hence, under each of these probabilities q $[0, q^*]$, the stock's (normalized) current value exceeds its expected future value, i.e. $S/R^{-1} > [quS + (1 - q)dS]$. In other words, the stock has a price process which is a super martingale because it cannot be sold short.

32.6 Other Types of Frictions

Due to limitations of space, we have so far considered primarily the case of no short sales. In this section, we briefly outline the impact of other types of frictions.

Consider an alternative formulation of a short sales constraint where the admissible extent of short sales of an individual asset varies with the value of the investor's portfolio and with any collateral pledged. Such a constraint recognizes that some assets (such as a very liquid, short-term Treasury bill) are judged to have "high" value as collateral, and thus better afford the ability to maintain a short position than is the case with other assets (such as an illiquid, off-the-run Treasury bond) deemed to have "low" collateral value. In such a setting, Hindy (1995) proved that the absence of arbitrage implies that every asset's price admits a decomposition into a dividend-based value and a residual that depends on the asset's "collateralizability." Thus, the law of one price may not hold: asset k may sell at a higher price than asset l even if their payoffs are the same if a one dollar worth of asset k allows investors the ability to short more of a third asset j than does a dollar worth of asset l.[5]

Transactions costs in trading some or all assets constitute yet another type of market friction. In a binomial stock price model with proportional transactions costs, Bensaid, et al. (1992), showed that even when an option's payoff can be exactly replicated, it can be cheaper to hedge an option with a strategy that results in a payoff that dominates that of the option when there are transactions costs. This result is foreshadowed in Boyle and Vorst (1992) who derive the cost of exactly hedging an option in an identical framework, and show that their hedge portfolio's cost is increasing in the number of trading periods for a high enough transaction cost parameter, and for options close to at-the-money–i.e. those which have a lot of convexity and whose exact replication requires a lot of rebalancing. Thus, the intuition from these papers is essentially that the benefits of exact replication can be traded off against savings on transactions costs. It should also be intuitively clear that in such settings that the cost of super-replicating a pool of payoffs may be cheaper than the sum of the costs of super-replicating the individual payoffs. In other words, the sublinearity result of Proposition 2 will continue to hold.

Conclusion

We have provided a review of the principal results which obtain when there are no arbitrage opportunities in a world where investors have to contend with market frictions. We conclude with some remarks about the consistency of these results with equilibrium.

One of the advantages of the no-arbitrage approach to valuation is that it allows one to make predictions about prices that are independent of particular investor attributes such as risk aversion, endowments etc. The reason is that the prices of the existing primitive assets effectively subsume the risk preferences of the marginal investor. Furthermore, in the absence of frictions, all investors' marginal utility-based valuations of all traded assets coincide: i.e. any investor may be taken to be the marginal agent supporting prices.

When there are frictions, investors' valuations may be heterogeneous, and hence differ from that predicted by the no-arbitrage approach. For instance, when there are short sales constraints, Chen (1995) showed that the price of a security derived from the no-arbitrage condition may be lower than the price that the seller of the security can actually receive by selling it to the investor who values it most. Furthermore, as Detemple and Murthy (1997) showed, the introduction of what may otherwise be considered redundant securities can upset a given equilibrium in the presence of constraints on portfolio weights. More recently, Hara (2000) shows that even when introduction of a new security does not change utility-maximizing consumption choices it may give rise to a multiplicity of each investor's security demands which in turn raises subtle equilibrium issues.

Thus, while routine application of the no-arbitrage approach in the presence of market frictions is not necessarily as useful as in a frictionless world, it nevertheless presents exciting new challenges for future research in asset pricing.

Notes
1. Some other papers relevant to arbitrage and market frictions, which we do not discuss are Dybvig and Ross (1986), Jarrow and O'Hara (1989), and Prisman (1986).
2. Other important types of market frictions include (a) a constraint on portfolio weights (such as that under a leverage constraint or margin restriction) where the

permitted amount of short sales or borrowing varies with the value of the portfolio, (b) unlimited short sales at a cost that increases with the extent of short sales, and (c) transactions costs that have either or both a fixed component and a variable component.

3. Given the availability of a risk-free bond, every payoff has such a minimum cost. Also note that each primitive asset must satisfy $\phi(D_j) = S_j(0)$, $j = 1,\ldots, J$, for if this were not true, they would not be held by any investor (which is incompatible with the fact that they are in positive net supply).

4. In this finite dimensional setting, the new probability measure associated with $\phi^{NS}(.)$ need not be equivalent to P; i.e. the new measure need not assign positive probabilities to the same states that P does. However, limiting arguments can be used in an infinite state space to establish equivalency.

5. Note that such a violation of the law of one price does not occur in Sections 32.4 and 32.5 where we considered a simpler type of short sales constraint.

Fundamental Tradeoffs in the Publicly Traded Corporation

33

Joseph P. Ogden

Abstract

This article discusses some fundamental cost-benefit tradeoffs involving publicly traded corporations from a corporate finance viewpoint. The fundamental benefits include greater access to capital at a lower cost and economies of scale. The potential costs are associated with two fundamental problems: principal–agent conflicts of interest and information asymmetry. Various mechanisms have evolved in the United States to mitigate these problems and their costs, so that the bulk of the fundamental benefits can be realized.

33.1 Introduction

This article discusses, from a corporate finance perspective, the fundamental benefits and costs associated with the publicly traded corporation as a form of business organization. The fundamental benefits are two-fold. First, by incorporating and attaining public-trading status a firm gains access to a large pool of capital, which it can use to pursue capital investment projects that take advantage of economies of scale. Second, a firm's cost of capital is reduced because public investors will accept a lower cost of capital, and this is so because investors are diversified and the firm's securities are more liquid.

Costs relate to two fundamental problems that beset the publicly traded corporation, both of which are consequences of the separation of ownership and control. The first problem involves "principal–agent conflicts of interest." The second problem is "information asymmetry." This article discusses these fundamental problems, their potential costs, and various mechanisms that have evolved in the United States to mitigate these problems and their costs, so that the bulk of the fundamental benefits can be realized.

33.2 Fundamental Benefits of the Publicly Traded Corporation

The fundamental benefits of the publicly traded corporation are two-fold. First, by attaining public-trading status, a firm gains access to the large pool of equity capital that is available in the public equity markets, and also enhances its access to credit markets for debt capital. Large amounts of capital allow a firm to pursue capital investment projects that take advantage of economies of scale, and thus are more profitable. Second, as many corporations emerge, secondary markets develop that allow investors to trade corporate securities and become diversified. In addition, secondary markets increase the value of corporate securities by increasing their liquidity and decreasing the cost of debt and equity capital, which in turn increase the assessed profitability of corporate projects.

33.2.1 Economies of Scale

All for-profit businesses are established to create value. The corporation is specially designed to create value on a large scale. A corporation is a separate legal entity, tethered to its owners by shares of stock. The two basic legal characteristics that distinguish a corporation from other forms of business (e.g. a sole proprietorship) are "limited liability" and the "separation of ownership and control." Regarding the first, the extent of stockholders' financial responsibility for the liabilities of a corporation that they collectively own is limited to the corporation's assets, and does not extend to the stockholders' personal assets. Regarding the second, in most corporations ownership is vested in one group, stockholders, while control is vested in another group, management (though, of course, managers may hold some of the firm's shares).

These two legal characteristics allow a corporation to create value efficiently and on a large scale. Limited liability allows many individuals to pool their capital without concern for legal complexities and inefficiencies that would be involved if the personal assets of each individual were involved. As Jensen and Meckling (1976) explain, with unlimited liability individual stockholders would need to monitor each other's wealth in order to estimate their own liability, which would be very costly if the firm's shares were widely held.

The separation of ownership and control allows the two basic inputs in any economy, capital and expertise, to be contributed by separate individuals. Some individuals have expertise to develop and undertake profitable real investments, but lack capital, whereas other individuals have capital, but lack the time and/or expertise to undertake profitable real investments. The corporation combines these two factors of production under a formal efficient structure.

Moreover, economies of scale are present in virtually all business activities, and are generally very large. Scale economies allow a larger firm, at least potentially, to create substantial value by reducing the cost of production. A corporation has the potential to amass large amounts of capital, which in turn allows it to pursue capital investment projects that take advantage of economies of scale, and thus are more profitable.

33.2.2 Reducing the Cost of Capital: Diversification and Liquidity

Two additional important benefits are associated with the publicly traded corporation: diversification and liquidity. To see these benefits, note that each firm in the economy can amass a large amount of capital by appealing to many investors to become stockholders. In turn, each investor can invest only a small portion of his or her investable wealth in any given firm, and therefore can invest in the equities of many firms simultaneously. Thus, investors can reduce the risk of their portfolios by diversifying across many firms. Risk-averse investors will accept a lower expected return on the equity of each firm because they can eliminate much of the risk of these investments via diversification. Consequently, each firm's cost of equity capital will be lower than would be the case if investors were not diversified. In turn, if all firms in the economy face a lower cost of equity capital, more projects will be deemed profitable (i.e., value-creating).

A security is liquid to the extent that an investor can quickly buy or sell the security at or near a fair price and at a low transaction cost. Liquidity is important to an investor because the ultimate purpose of investment is to provide for future consumption, either sooner or later. Investors will accept a lower expected return on equity (and thus firms will enjoy a lower cost of equity capital) if equities are liquid. The liquidity of securities naturally follows from investors' desire to become diversified. This is so because secondary markets will develop to allow trading in securities. (For additional discussion, see Ogden et al., 2003, pp. 76–77).

33.3 Fundamental Costs of the Publicly Traded Corporation

According to Modern Corporate Finance Theory, two fundamental problems beset the publicly traded corporation: "principal–agent conflicts of interest and information asymmetry." These problems are important because they can potentially impose costs that are sufficiently large as to threaten the fundamental benefits discussed in the previous section. This section discusses these problems and their costs. The next section discusses various mechanisms designed to alleviate these problems, and thus to mitigate their costs.

33.3.1 Principal–Agent Conflicts of Interest

The first fundamental problem concerns the relationship between a principal and an agent. In general, a principal hires an agent to act in the principal's interest by performing a specified task. A problem arises in that the agent is hired to act in the principal's interest and yet, as a self-interested human being, the agent cannot be expected to subordinate his or her own interests. Thus, a conflict of interest naturally arises between the principal and the agent. In corporate finance, two types of principal–agent conflicts of interest are paramount: (1) conflicts between a firm's stockholders (as principals) and its management (as agents); and (2) conflicts between the firm (as an agent) and its creditors (as principals).

Regarding conflict (1), a firm's management is hired to act in the stockholder's interest, which is generally assumed to maximize the market value of the firm's equity. However, managers are ultimately interested in maximizing their own

welfare and they control the firm. As noted earlier, an important feature of the corporation is the separation of ownership and control, and this feature is critical to capturing the stated fundamental benefits.

Managers have a self-serving incentive to capture "private benefits of control." The following are among the activities that management might employ to capture such benefits: (a) excessive consumption of "perquisites," (b) manipulating earnings and dividends, (c) maximizing the size of the firm, rather than the market value of its equity, (d) siphoning corporate assets, (e) excessive diversification at the corporate level, (f) a bias toward investments with near-term payoffs, (g) underemployment of debt, (h) entrenching their positions, and (i) packing the firm's board of directors with cronies. (For a discussion of these activities, see Ogden et al., 2003, pp. 83–88.) In the absence of mechanisms (discussed later) to offset management's private incentives, the costs to stockholders of such activities can be sufficiently large as to negate the stated fundamental benefits of the publicly traded corporation.

In addressing conflict (2), we generally assume that the conflict of interest between stockholders and management is resolved. Instead, we focus on a conflict of interest between the firm and its creditors. In this context, a creditor can be seen as a principal who "hires" the firm as an agent (i.e. by paying money up-front in the form of a loan) to act in the creditor's interest (i.e. to operate the firm in a manner that ensures that timely interest and principal payments will be made to the creditor.)

A conflict arises in that the firm's management, who will be controlling the firm, is hired to act in the stockholders' interest, rather than the creditor's interest. In the absence of mechanisms (discussed later) to protect the creditor's interest, management may engage in any of the following activities that serve to expropriate wealth from a creditor to stockholders: (a) increasing leverage, especially by subsequently issuing additional debt that has equal priority to the firm's original debt, (b) increasing the riskiness of the firm's operations (the "asset substitution" or "risk-shifting" problem), and (c) paying dividends. (For a discussion of these activities, see Ogden et al., 2003, pp. 88–93).

In addition, Myers (1977) identifies an important deadweight cost of debt called the "underinvestment problem" or the "debt overhang problem." If a firm has default-risky debt outstanding and a profitable investment opportunity that must be financed with equity, the firm's management might forego the investment even though it is profitable per se. This can occur if a sufficient portion of the net present value (NPV) of the project transfers to the creditors (i.e. creditors are made better off by the adoption of the project) such that the net benefit to stockholders (i.e. net of their cash contribution) is negative.

33.3.2 Information Asymmetry

The second fundamental problem is called the "information asymmetry" problem. Akerlof (1970) is generally credited with recognizing information asymmetry as a general problem in a market, though its application to corporate finance was quickly recognized. To illustrate the problem, Akerlof refers to the market for used automobiles. The crux of the problem is that the quality of a particular used make and model of automobile varies across the units for sale, and sellers know more about the quality of their unit than do potential buyers. Sellers of low-quality units have an incentive to make minimal repairs and otherwise exaggerate the quality of their unit to mimic the better-quality units in the market. As a result, in equilibrium all units will share a common price, which reflects the (true) average quality of units for sale. However, this equilibrium is unsustainable because some or all of the sellers of (truly) better-quality units will exit the market. After they exit, the true average quality of units in the market is lower, and thus so must the common price. This process will continue until only the "lemons" remain in the market. In short, the market for used automobiles can collapse under the weight of information asymmetry. (See Ogden et al., 2003, pp. 101–102).

The markets for corporate securities are also naturally beset by information asymmetry because of product market competition and the separation of ownership and control. A firm's management (assumed to be acting in the stockholders' interest) must devise strategic plans to compete in its chosen product market. These plans cannot be divulged to the firm's diffuse stockholders for the simple reason that this would be tantamount to revealing the information to the firm's competitors, who could surreptitiously become stockholders in order to gain access to such plans, and then thwart them with counter-strategies.

Consequently, a firm's management generally and necessarily has more information about the firm's operations, and thus its true value, than do the firm's actual or potential stockholders. In the absence of mechanisms (discussed below) to mitigate this information asymmetry problem, the market for corporate securities may be very poor,- and could even collapse àla Akerlof's argument.

33.4 Mitigating the Costs

A wide variety of mechanisms have emerged in the U.S. and other markets to mitigate costs associated with both the agency and information asymmetry problems discussed above. This section briefly discusses such mechanisms, following a top-down approach. (For an in-depth discussion of each of these mechanisms, see Ogden et al., 2003, Chapter 5).

33.4.1 Government Laws and Regulations

The most fundamental services that government provides are for establishment of property rights through legislation and the enforcement of legal contracts through a judicial system. In addition, government generally regulates the financial markets, such as with the US Securities Act of 1933 and the Securities Exchange Act of 1934, the latter of which established the Securities and Exchange Commission (SEC). The SEC requires all firms with publicly traded securities to register such securities, to file periodic financial statements, etc. The 1934 act also requires publicly traded firms to provide stockholders the opportunity to vote on matters such as the election of board directors. The SEC also prohibits insider trading, requires major owners of a firm's equity to disclose their ownership, etc. The regulations imposed by the SEC most obviously help to reduce information asymmetry and associated costs. In addition, these regulations curb the self-serving activities of managers, and thus help to mitigate costs associated with principal–agent conflicts of interest.

33.4.2 Securities Traders, Analysts, and the Press

Securities traders, analysts, and the press all generate important information about the values of securities and the efficacy of firms' managements. Their efforts help to reduce information asymmetry. In addition, they serve as indirect monitors of each firm's management, which curbs management's opportunities to engage in self-serving activities, and thus mitigates costs associated with stockholder–management conflicts of interests.

33.4.3 Ownership Structure

A firm's stockholders can promote their own interest through "activism," specifically, by voting on major management-initiated proposals, submitting their own proposals, and monitoring management's decisions. Unfortunately, if a firm's ownership is diffuse, activism is generally thwarted by the "free-rider problem," whereby stockholders have an incentive to freely benefit from the costly efforts of others to monitor and reform management.

One means of mitigating the free-rider problem is for a firm's equity to be closely held (i.e. by nonmanagement stockholders), so that most or all of a firm's stockholders have a sufficient financial incentive to monitor management. However, close ownership is costly because it reduces the benefits of the corporate form discussed earlier. Alternatively, a firm may require management to own a substantial number of the firm's shares (or to hold stock options), which serves to align stockholders' and management's interests. However, this mechanism is also imperfect. For instance, if the bulk of a manager's personal portfolio is invested in the manager's own firm, his or her financial policies (i.e. real investment and financial decisions) may be distorted in a way that reduces the value of the firm's shares.

33.4.4 Board Oversight

Board directors are hired to protect and promote the interests of a firm's stockholders. The existence of boards of directors is perhaps the most obvious indication of a potential conflict of interest between stockholders and management. An independent board can be an effective advocate of stockholders' interests because the board generally has powers to: (1) require board approval of major capital expenditures, acquisitions, divestitures, and security offerings, (2) control the firm's capital structure, (3) hire outside consultants to scrutinize major projects, and (4) as necessary, fire senior management.

However, senior management has an incentive to "pack the board" with its cronies. If management is successful in doing so, the board becomes little more than a "rubber stamp" for management's decisions. To avoid this, stockholders should insist on an independent board, consisting of mostly outsiders who are not beholden to management.

33.4.5 Financial Institutions

A wide variety of financial institutions exist in the United States, including commercial banks, finance companies, insurance companies, venture capital firms, and securities firms (i.e. underwriters). According to theory, one of the most fundamental services provided by financial institutions is to mitigate costs associated with the information asymmetry problem in the market for corporate securities. Sellers of valuable proprietary information work through a financial institution that acts as an "intermediary" between the firm and investors. The intermediary is in a position to verify the value of the proprietary information, and yet can be trusted to keep such information confidential.

33.4.6 Contract Devices

Finally, firms employ a variety of contract devices to mitigate principal–agent conflicts of interest and/or information asymmetry problems. To illustrate, we briefly discuss two

types of contracts that can alleviate conflicts: executive compensation contracts and debt contracts.

For a firm with diffuse ownership, devising a contract with senior management is problematic because managers have private incentives to maximize their own welfare, as discussed earlier. In order to align the interests of stockholders and management, a firm may include performance-based provisions in the executive's compensation contract, such as an annual earnings-based bonus or grants of stock or stock options. Such provisions may serve the intended purpose reasonably well, but could also backfire by causing management to distort the firm's capital investment program, its capital structure, its dividend policy, etc.

We also mentioned earlier that a conflict of interest arises between a borrowing firm and its creditors, whereby the firm has an incentive to take actions to expropriate wealth from creditors. Creditors can mitigate these incentives by including various provisions and covenants in the debt contract. For instance, a creditor may demand collateral to mitigate the asset substitution problem. Creditors may also restrict the firm's ability to issue additional debt and to restrict or prohibit the payment of dividends.

33.4.7 Signaling

Finance theory also suggests that firms can provide "signals" of true value to the market in order to mitigate the information asymmetry problem. In the finance literature, authors have suggested each of the following signaling mechanisms: ownership structure, leverage, dividends, and stock repurchases. (For discussion, see Ogden et al., 2003, Chapter 4).

33.5   Summary

This article discusses fundamental tradeoffs associated with the publicly traded corporation. On the positive side, corporations allow for the concentration of large quantities of capital, which can be used for investing in large capital investment projects that capture valuable economies of scale. In addition, the corporate form allows investors to diversify and to trade securities, which reduces the cost of capital. On the negative side, the separation of ownership and control engenders two fundamental and potentially costly problems: principal–agent conflicts of interest and information asymmetry. Various mechanisms have evolved at various levels to mitigate these problems and their costs, so that more of the fundamental benefits of the publicly traded corporation can be realized.

The Mexican Peso Crisis

34

Fai-Nan Perng

Abstract

The Mexican Peso Crisis was the byproduct of various developments including large inflows of short-term foreign capital, prolonged current account deficit, and political instability. Between 1990 and 1993, investors in the United States were particularly eager to provide loans, many of them short-term, to the Mexican government and to Mexican corporations. Throughout this period, the share of foreign capital inflows exceeded the current account deficit. However, political instability and U.S. interest rate hikes soon changed the optimism for Mexico's economic outlook. At the beginning of 1994, this did not affect the value of the peso, for Mexico was operating with a target zone exchange rate and its central bank stood ready to accept pesos and pay out dollars at the fixed rate. Yet Mexico's reserves of foreign currency were too small to maintain its target zone exchange rate. When Mexico ran out of dollars at the end of 1994, the Mexican government announced a devaluation of the peso. As a result, investors avoided buying Mexican assets, adding to downward pressure on the peso.

Overall, the Mexican meltdown of 1994–1995 had many facets. Yet couple of lessons are particularly clear: while foreign capital can make up for the shortfall in domestic saving, only long-term capital – in the forms of foreign direct investment or long-term debt – is conducive to domestic investment; large and abrupt movements of capital across national borders can cause excessive financial market volatility and undermine economic stability in the countries involved. Last and most importantly, prolonged current account deficit should be remedied by allowing the domestic currency to depreciate, promoting savings, or cutting back government expenditure rather than financed by foreign capital inflows. Countries with protracted current account deficits such as Argentina, the Philippines, Indonesia, Thailand, and Saudi Arabia, with Thailand in particular, should heed Mexico's experience.

Mr. Perng, the Governor of Taiwan's central bank, noted the long running current account deficits for a number of Asian countries in his article published in the Commercial Times on 23 February 1995. He stated that the situation in Thailand was especially worrisome as its current account deficit was mainly financed by short-term financial capital inflows. Fifteen months after the publication of this article, the Asian financial crisis broke out with Thailand at the front line of the crisis.

[b]As published by Mexico's central bank in its monetary policy report on 25 January 1995

The Mexican government stopped repaying external debt obligations in August 1982 due to a shortfall of its foreign exchange reserves. Brazil, Argentina, and Chile followed suit, which triggered what came to be known as the Latin American Debt Crisis. Later, following a series of economic and financial reforms, conditions in Mexico gradually improved sufficiently to start attracting inward investment again. The debt relief initiative put forth by U.S. Treasury Secretary Nicholas Brady in 1990 eventually put Mexico more firmly back on her feet. Thereafter, Mexico engaged in several rounds of negotiations with the United States with the intent of securing the North American Free Trade Agreement and eventually won the U.S. Congress over toward the end of 1993. It is fair to say that in the years between 1990 and 1993, most foreign investors were bullish about the outlook of the Mexican economy.

In a separate development, the advancement of telecommunications and computer technology has sped and immensely reduced the cost of transferring capital. Moreover, a growing number of households started to entrust their savings with professional fund managers. Portfolios managed by fund managers tend to be well diversified with assets invested in multiple currencies (huge sums of money can literally be moved from one currency to another or one financial product to the next at the push of a button), a practice that further hastened the speed and amplified the magnitude of international capital movements (the combined value of cross-border portfolio investment in Europe, America, and Japan reached $2,500 billion in 1991).

While this was taking place, the U.S. economy was mired in a protracted downturn. The Federal Reserve rightly countered with a monetary stimulus. The interest rate on the 3-month fixed deposits was slashed from 10.25% in March 1989 to 3.1875% in January 1994. Against the backdrop of highly efficient international financial markets, U.S. investors moved a huge chunk of their capital abroad. A significant portion of this outflow was absorbed by emerging markets in Latin America including, of course, Mexico.

Owing to the various developments outlined in the preceding paragraphs, substantial foreign capital began to flow into Mexico in 1990. The size of foreign capital inflow ballooned from $8.441 billion in 1990 to $32.06 billion by 1993. Altogether, some $92.647 billion of foreign capital swamped Mexico's financial markets in those 4 years (Table 34.1).

Among the first to be affected by this foreign capital inflow was, not surprisingly, the Peso. At that time, Mexico's exchange rate system was one of target zone. The lower bound of the Peso/USD exchange rate had been set at 3.05 since November 1991 when foreign exchange controls were removed. The upper bound had been raised gradually at a rate of 0.0004 Peso per day, beginning on 21 October 1992. The idea was to allow the Peso/USD exchange rate to adjust within a band wide enough to properly reflect supply and demand in the foreign exchange market (Figure 34.1).

Before the end of 1993, the Peso/USD exchange rate was relatively stable due to large and sustained foreign capital
PESO/US$

Fig. 34.1 Peso/US$ exchange rate

inflows that more than offset current account deficits. Under this arrangement, the integrity of Mexico's target zone exchange rate regime was not put to test. At the same time, the Mexican inflation rate was running at a significantly higher level than that of the United States. Between 1990 and September 1994, the U.S. CPI rose by only 4%. During the same period, the Mexican CPI jumped by 61.3%. In a parallel development, the Peso depreciated from 2.9454 to 3.4040 to a dollar. According to the purchasing power parity, the Peso/USD exchange rate should have been 4.5682 in

Table 34.2 Peso/US$ exchange rate and inflation comparison

	1990	1991	1992	1993	1994/9

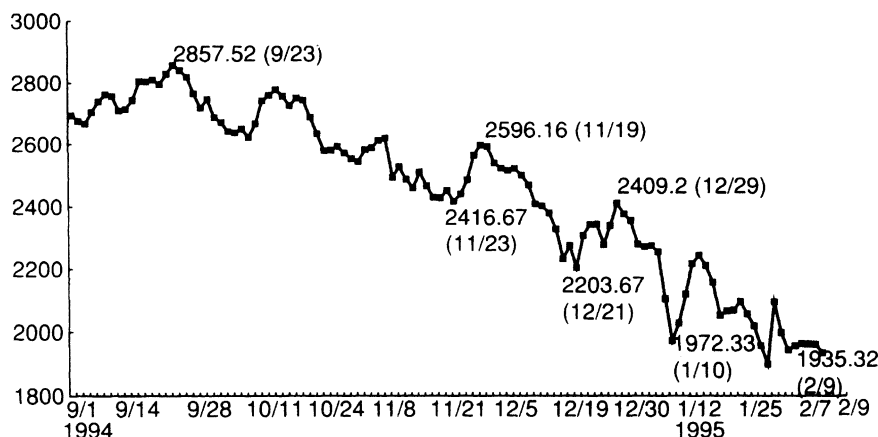
September 1994. In other words, the Peso was overvalued by 34% (Table 34.2 and Figure 34.2).

Maintaining a stable Peso/USD exchange rate helped to push the Mexican inflation down, as American prices were stable. Mexican CPI inflation was 23.3% in 1990, which dropped to 8.4% by September 1994. An overvalued Peso, however, undermined the competitiveness of Mexican exports. It's a small wonder that the position of the current account continued to worsen. A deficit of $7.451 billion in 1990 swelled to $23.391 billion in 1993, a figure approaching 6% of Mexico's GDP. For 1994, this figure was projected to rise to $28 billion or 8% of Mexico's GDP (Table 34.1).

Throughout this period, the share of foreign capital inflows that exceeded the current account deficit was bought by the central bank. This would explain why Mexico's foreign exchange reserves rose from $5.946 billion in 1989 to $24.886 billion by the end of 1993 (Table 34.1).

At the beginning of 1994, for a variety of reasons, investor confidence began to wane. External factors include U.S. interest rate hikes that started from February 1994 and the resulting rise in the rate of return from investing in the dollar, which were inarguably the most important. Explanations that had roots at home include the January 1994 riot in the southern province of Chiapas, the assassination of Señor Colosios, the ruling party's presidential candidate in March, and the deterioration of the current account deficit. No longer upbeat about the prospect of the Mexican economy and recognizing that the Peso/USD exchange rate had become unstable, foreign capital inflow dried up to a level that could no longer sustain the current account deficit. Demand for the U.S. dollar far exceeded the supply in the foreign exchange market; the Peso sapped. In order to keep the Peso exchange rate within the upper bound of the target zone, the Mexican government intervened heavily by selling the dollar, a process that quickly depleted precious foreign exchange reserves. In order to replenish official reserves that were running at a dangerously low level, Mexico issued the Tesobonos, a U.S. dollar-denominated short-term debt payable in Peso at maturity. In retrospect, Mexico's central bank should have tightened its monetary stance. But instead, it acted like an innocent bystander, fearing such measures would dampen economic growth and hoping that foreign investors will return in droves after the presidential election in August. Although the ruling party did get re-elected, its secretary general, Señor Masssieu, was assassinated in September. When the newly elected President Zedillo was sworn into office on December 1, Mexico's financial markets were on the brink of collapse.

Among the many forces that were weighing on Mexico's financial markets, the overvalued Peso and the accompanying deterioration in the current account deficit were the most obvious. Another key feature of the Mexican debacle was that foreign capital inflows had predominantly been invested in short-term debts. Of the $32 billion worth of capital inflow in 1993, $27.9 billion was invested in such instruments (Table 34.1). The source of this type of foreign capital inflow

Fig. 34.3 Mexican stock index


can be traced to mutual funds (Fidelity alone had $8 billion invested in emerging markets in 1994), and hedge and pension funds. All it took was one telephone call for the funds to be shifted out of Mexico once the fund managers convinced themselves that the Peso exchange rate was unstable or when the sentiment on the outlook of the Mexican economy suddenly turned bearish.

With the current account position worsening and the inflow of foreign capital reduced to a trickle, the Mexican government resorted to financing the current account deficit with official reserves in addition to issuing short-term dollar debts and the Tesobonos. Mexico's foreign exchange reserves declined from $24.886 billion at the end of 1993 to $11.15 billion on 16 December 1994. Although Señor Serra, the finance minister, repeatedly reassured foreign investors that the upper bound of the peso exchange rate would not be breached, that very ceiling was hastily raised from 3.4712 to 4.0016 on 20 December. The Peso exchange rate fell sharply from 3.4647 at the close of the business day on December 20 to 3.9750 the next day, getting uncomfortably close to the 4.0016 mark. Unable to stem the tide of foreign capital outflow and with the level of foreign exchange reserves running precariously low, the Mexican government had little choice but to let the Peso float (Figure 34.1). The Peso fell to an all-time low of 5.5 to a dollar on 28 December.

The exodus of foreign capital not only exerted a severe downward pressure on the Peso exchange rate but also depressed stock prices. The Mexican stock index fell from 2857.5 on 23 September 1994 to 1935.32 on 9 February 1995, or 32% in 4 months (Figure 34.3).

For a variety of reasons, the United States came to Mexico's rescue and brought the international financial community to the negotiating table. Possible explanations for the action taken by the U.S. government include:

1. As much as $53 billion of debt was about to become due at the end of 1995. Unaided, Mexico was in eminent danger of repeating the 1982 crisis.
2. Mexico had become United States' third largest trading partner, with bilateral trade amounting to $100 billion per

annum. A further deterioration in the Mexican economy was more than likely to have a negative impact on the United States; the number of illegal immigrants waiting to cross the border could rise considerably.
3. The contagion effect of the Mexican crisis was beginning to be felt by other large Latin American debtors such as Brazil and Argentina. Helping Mexico would prevent the contagion from spreading further afield.
4. The aid package included broad based economic stabilization measures (putting a 7% cap on wage increases, cutting back government expenditure, and curbing the expansion of bank credits and money supply).

President Bill Clinton's proposal to provide a $40 billion loan guarantee that would have enabled Mexico to raise fresh capital in international financial markets and resume debt repayment was rejected by the U.S. Congress on 30 January. The Peso took the hit and tumbled to 6.35 to a dollar the next day. By then, Mexico had only enough foreign exchange reserves to last two more days. In an emergency session, the United States, Germany, and France finally agreed to provide Mexico with a $48.8 billion refinancing package, the details of which are as follows:

1. The U.S. government would establish a $20 billion credit line (with $1.4 billion coming from the Exchange Stabilization Fund of the Department of Treasury) made up of:
   (a) A Peso/dollar swap line for maturities that fall within 12 months or between 3 and 5 years
   (b) Guarantee for debts with maturities up to 10 years designed to help Mexico to raise new debts in international markets.
   The remaining $600 million came in the form of a temporary short-term swap credit line set up by the U.S. Federal Reserve.
2. The IMF offered a $17.8 credit line of which $7.8 billion came in the form of emergency credits and a $10 billion stand-by credit facility financed by emerging market economies with ample foreign exchange reserves.
3. The Bank for International Settlements chipped in with a $10 billion credit line consisting of swap facilities offered

by its 29 member central banks (including the United States, Japan, Germany, UK, and France).

4. Argentina, Mexico, Chile, and Colombia collectively offered a $1 billion credit line.

The combined value of the four credit lines listed above summed to $48.8 billion. Meanwhile, a consortium of private sector financial institutions headed by Citibank and JP Morgan negotiated for a syndication loan worth $3 billion.

The following lessons can be learnt from the Mexican financial crisis:

1. Capital formation can promote economic growth, but the most reliable source of fund is domestic savings. While foreign capital can make up for the shortfall in domestic savings, only long-term capital, in the forms of foreign direct investment or long-term debt, is conducive to domestic investment. Foreign portfolio investment channels funds into secondary markets, resulting in the transfer of ownership, but brings little direct benefit to domestic capital formation.

2. The size of global portfolio investment has grown exponentially. Fund managers make investment decisions based on predictions about future exchange rates, interest differentials, and stock prices. Large and abrupt movements of capital across national borders can cause excessive financial market volatility and undermine economic stability in the countries involved. These adverse effects would be especially acute in small but highly open economies. For this reason, capital account liberalization should follow a gradual and orderly approach.

3. Prolonged current account deficit should be remedied (by allowing the domestic currency to depreciate, promoting saving, or cutting back government expenditure) rather than financed by foreign capital inflows. A country cannot rely on external financing indefinitely. Interestingly enough, countries like Argentina, the Philippines, Indonesia, Thailand, and Saudi Arabia have all been running current account deficits since 1987. It is worth pointing out that Thailand, in particular, relies almost exclusively on short-term capital inflows to finance her current account deficit.

4. The IMF should acquire in-depth knowledge of member economies, work with them to establish an early warning system, and make policy recommendations that would prevent the outbreak of future crises.

Portfolio Performance Evaluation

35

Lalith P. Samarakoon and Tanweer Hasan

Abstract

The portfolio performance evaluation involves the determination of how a managed portfolio has performed relative to some comparison benchmark. Performance evaluation methods generally fall into two categories, namely conventional and risk-adjusted methods. The most widely used conventional methods include benchmark comparison and style comparison. The risk-adjusted methods adjust returns in order to take account of differences in risk levels between the managed portfolio and the benchmark portfolio. The major methods are the Sharpe ratio, Treynor ratio, Jensen's alpha, Modigliani and Modigliani, and Treynor Squared. The risk-adjusted methods are preferred to the conventional methods.

35.1 Introduction

The portfolio performance evaluation primarily refers to the determination of how a particular investment portfolio has performed relative to some comparison benchmark. The evaluation can indicate the extent to which the portfolio has out-performed or under-performed, or whether it has performed at par with the benchmark.

The evaluation of portfolio performance is important for several reasons. First, the investor, whose funds have been invested in the portfolio, needs to know the relative performance of the portfolio. The performance review must generate and provide information that will help the investor to assess any need for rebalancing of his investments. Second,

the management of the portfolio needs this information to evaluate the performance of the manager of the portfolio and to determine the manager's compensation, if that is tied to the portfolio performance. The performance evaluation methods generally fall into two categories, namely conventional and risk-adjusted methods.

35.2 Conventional Methods

35.2.1 Benchmark Comparison

The most straightforward conventional method involves comparison of the performance of an investment portfolio against a broader market index. The most widely used market index in the United States is the S&P 500 index, which measures the price movements of 500 U.S. stocks compiled by the Standard & Poor's Corporation. If the return on the portfolio exceeds that of the benchmark index, measured during identical time periods, then the portfolio is said to have beaten the benchmark index. While this type of

L.P. Samarakoon (✉)
University of St. Thomas, Minneapolis, MN, USA
e-mail: lpsamarakoon@stthomas.edu

T. Hasan
Roosevelt University, USA

comparison with a passive index is very common in the investment world, it creates a particular problem. The level of risk of the investment portfolio may not be the same as that of the benchmark index portfolio. Higher risk should lead to commensurately higher returns in the long term. This means if the investment portfolio has performed better than the benchmark portfolio, it may be due to the investment portfolio being more risky than the benchmark portfolio. Therefore, a simple comparison of the return on an investment portfolio with that of a benchmark portfolio may not produce valid results.

35.2.2 Style Comparison

A second conventional method of performance evaluation called "style-comparison" involves comparison of return of a portfolio with that having a similar investment style. While there are many investment styles, one commonly used approach classifies investment styles as value versus growth. The "value style" portfolios invest in companies that are considered undervalued on the basis of yardsticks such as price-to-earnings and price-to-book value multiples. The "growth style" portfolios invest in companies whose revenue and earnings are expected to grow faster than those of the average company.

In order to evaluate the performance of a value-oriented portfolio, one would compare the return on such a portfolio with that of a benchmark portfolio that has value-style. Similarly, a growth-style portfolio is compared with a growth-style benchmark index. This method also suffers from the fact that while the style of the two portfolios that are compared may look similar, the risks of the two portfolios may be different. Also, the benchmarks chosen may not be truly comparable in terms of the style since there can be many important ways in which two similar style-oriented funds vary.

Reilly and Norton (2003) provide an excellent disposition of the use of benchmark portfolios and portfolios style and the issues associated with their selection. Sharpe (1992), and Christopherson (1995) have developed methods for determining this style.

35.3 Risk-Adjusted Methods

The risk-adjusted methods make adjustments to returns in order to take account of the differences in risk levels between the managed portfolio and the benchmark portfolio. While there are many such methods, the most notables are the Sharpe ratio (S), Treynor ratio (T), Jensen's alpha (α), Modigliani and Modigliani (M^2), and Treynor Squared (T^2).

These measures, along with their applications, are discussed below.

35.3.1 Sharpe Ratio

The Sharpe ratio (Sharpe, 1966) computes the risk premium of the investment portfolio per unit of total risk of the portfolio. The risk premium, also known as excess return, is the return of the portfolio less the risk-free rate of interest as measured by the yield of a Treasury security. The total risk is the standard deviation of returns of the portfolio. The numerator captures the reward for investing in a risky portfolio of assets in excess of the risk-free rate of interest while the denominator is the variability of returns of the portfolio. In this sense, the Sharpe measure is also called the "reward-to-variability" ratio. Equation 35.1 gives the Sharpe ratio:

$$S = \frac{r_p - r_f}{\sigma_p} \qquad (35.1)$$

where S is the Sharpe ratio, r_p the return of the portfolio, r_f the risk-free rate, and σ_p the standard deviation of returns of the portfolio.

The Sharpe ratio for an investment portfolio can be compared with the same for a benchmark portfolio such as the overall market portfolio. Suppose that a managed portfolio earned a return of 20% over a certain time period with a standard deviation of 32%. Also assume that during the same period the Treasury bill rate was 4%, and the overall stock market earned a return of 13% with a standard deviation of 20%. The managed portfolio's risk premium is $(20 - 4\%) = 16\%$, while its Sharpe ratio, S, is equal to 16/32% = 0.50. The market portfolio's excess return is $(13 - 4\%) = 9\%$, while its S equals 9/20% = 0.45. Accordingly, for each unit of standard deviation, the managed portfolio earned a risk premium of 0.50%, which is greater than that of the market portfolio of 0.45%, suggesting that the managed portfolio outperformed the market after adjusting for total risk.

35.3.2 Treynor Ratio

The Treynor ratio (Treynor, 1965) computes the risk premium per unit of systematic risk. The risk premium is defined as in the Sharpe measure. The difference in this method is in that it uses the systematic risk of the portfolio as the risk parameter. The systematic risk is that part of the total risk of an asset which cannot be eliminated through diversification. It is measured by the parameter known as 'beta' that represents the slope of the regression of the returns of the managed portfolio on the returns to the market portfolio. The Treynor ratio is given by the following equation:

$$T = \frac{r_p - r_f}{\beta_p} \qquad (35.2)$$

where T is the Treynor ratio, r_p the return of the portfolio, r_f the risk-free rate, and β_p the beta of the portfolio.

Suppose that the beta of the managed portfolio in the previous example is 1.5. By definition, the beta of the market portfolio is equal to 1.0. This means the managed portfolio has one-and-half times more systematic risk than the market portfolio. We would expect the managed portfolio to earn more than the market because of its higher risk. In fact, in the above example, the portfolio earned an excess return of 16% whereas the market earned only 9%. These two numbers alone do not tell anything about the relative performance of the portfolio since the portfolio and the market have different levels of market risk. In this instance, the Treynor ratio for the managed portfolio equals $(20 - 4\%)/1.5 = 10.67$, while that for the market equals $(13 - 4\%)/1.00 = 9.00$. Thus, after adjusting for systematic risk, the managed portfolio earned an excess return of 10.67% for each unit of beta while the market portfolio earned an excess return of 9.00% for each unit of beta. Thus, the managed portfolio outperformed the market portfolio after adjusting for systematic risk.

35.3.3 Jensen's Alpha

Jensen's alpha (Jensen, 1968) is based on the Capital Asset Pricing Model (CAPM) of Sharpe (1964), Lintner (1965), and Mossin (1966). The alpha represents the amount by which the average return of the portfolio deviates from the expected return given by the CAPM. The CAPM specifies the expected return in terms of the risk-free rate, systematic risk, and the market risk premium. The alpha can be greater than, less than, or equal to zero. An alpha greater than zero suggests that the portfolio earned a rate of return in excess of the expected return of the portfolio. Jensen's alpha is given by.

$$\alpha = r_p - [r_f + \beta_p(r_m - r_f)] \qquad (35.3)$$

where α is the Jensen's alpha, r_p the return of the portfolio, r_m the return of the market portfolio, r_f the risk-free rate, and β_p the beta of the portfolio.

Using the same set of numbers from the previous example, the alpha of the managed portfolio and the market portfolio can be computed as follows. The expected return of the managed portfolio is $4\% + 1.5(13 - 4\%) = 17.5\%$. Therefore, the alpha of the managed portfolio is equal to the actual return less the expected return, which is $20 - 17.5\% = 2.5\%$. Since we are

measuring the expected return as a function of the beta and the market risk premium, the alpha for the market is always zero. Thus, the managed portfolio has earned a 2.5% return above that must be earned given its market risk. In short, the portfolio has a positive alpha, suggesting superior performance.

When the portfolio is well diversified all three methods – Sharpe, Treynor, and Jensen – will give the same ranking of performance. In the example, the managed portfolio outperformed the market on the basis of all three ratios. When the portfolio is not well diversified or when it represents the total wealth of the investor, the appropriate measure of risk is the standard deviation of returns of the portfolio, and hence the Sharpe ratio is the most suitable. When the portfolio is well diversified, however, a part of the total risk has been diversified away and the systematic risk is the most appropriate risk metric. Both Treynor ratio and Jensen's alpha can be used to assess the performance of well-diversified portfolios of securities. These two ratios are also appropriate when the portfolio represents a sub-portfolio or only a part of the client's portfolio. Chen and Lee (1981, 1986) examined the statistical distribution of Sharpe, Treynor, and Jensen measures and show that the empirical relationship between these measures and their risk proxies is dependent on the sample size, the investment horizon and market conditions. Cumby and Glen (1990), Grinblatt and Titman (1994), Kallaberg et al. (2000), and Sharpe (1998) have provided evidence of the application of performance evaluation techniques.

35.3.4 Modigliani and Modigliani Measure

The Sharpe ratio is not easy to interpret. In the example, the Sharpe ratio for the managed portfolio is 0.50, while that for the market is 0.45. We concluded that the managed portfolio outperformed the market. The difficulty, however, is that the differential performance of 0.05 is not an excess return. Modigliani and Modigliani (1997) measure, which is referred to as M^2, provides a risk-adjusted measure of performance that has an economically meaningful interpretation. The M^2 is given by

$$M^2 = r_{p*} - r_m \qquad (35.4)$$

where M^2 is the Modigliani-Modigliani measure, r_p^* the return on the adjusted portfolio, r_m the return on the market portfolio.

The adjusted portfolio is the managed portfolio adjusted in such a way that it has the same total risk as the market portfolio. The adjusted portfolio is constructed as a combination of the managed portfolio and risk-free asset, where weights are specified as in Equations 35.5 and 35.6.

$$w_{r_p} = \frac{\sigma_m}{\sigma_p} \quad (35.5)$$

$$w_{r_f} = 1 - w_{r_p} \quad (35.6)$$

where w_{rp} represents the weight given to the managed portfolio, which is equal to the standard deviation of the market portfolio (σ_m) divided by the standard deviation of the managed portfolio (σ_p). w_{rf} is the weight on the risk-free asset and is equal to one minus the weight on the managed portfolio. The risk of the adjusted portfolio (σ_p^*) is the weight on the managed portfolio times the standard deviation of the managed portfolio as given in Equation 35.7. By construction, this will be equal to the risk of the market portfolio.

$$\sigma_{p*} = w_{r_p} \times \sigma_p = \frac{\sigma_m}{\sigma_p} \times \sigma_p = \sigma_m \quad (35.7)$$

The return of the adjusted portfolio (r_p^*) is computed as the weighted average of the returns of the managed portfolio and the risk-free rate, where the weights are as in Equations 35.5 and 35.6 above:

$$r_{p*} = w_{r_f} \times r_f + w_{r_p} \times r_p \quad (35.8)$$

The return on the adjusted portfolio can be readily compared with the return on the market portfolio since both have the same degree of risk. The differential return, M^2, indicates the excess return of the managed portfolio in comparison to the benchmark portfolio after adjusting for differences in the total risk. Thus, M^2 is more meaningful than the Sharpe ratio.

In the example, the standard deviation of the managed portfolio is 32% and the standard deviation of the market portfolio is 20%. Hence, the $w_{rp} = 20/32 = 0.625$, and $w_{rf} = 1–0.625 = 0.375$. The adjusted portfolio would be 62.5% invested in the managed portfolio and 37.5% invested in Treasury bills. Now the risk of the adjusted portfolio, $\sigma_p^* = 0.625 \times 32\% = 20\%$, is the same as the risk of the market portfolio. The return on the adjusted portfolio would be $r_p^* = 0.375 \times 4\% + 0.625 \times 20\% = 14\%$. The $M^2 = 14 - 13\% = 1\%$. Thus, on a risk-adjusted basis, the managed portfolio has performed better than the benchmark by 1%.

35.3.5 Treynor Squared

Another performance measure, called T^2 analogous to M^2, can be constructed. This is a deviant of the Treynor measure, and the rationale is the same as that of M^2. T^2 is defined as

$$T^2 = r_{p*} - r_m \quad (35.9)$$

where T^2 is the Treynor-squared measure, r_p^* the return on the adjusted portfolio, and r_m the return on the market portfolio.

The adjusted portfolio is the managed portfolio adjusted such that it has the same degree of systematic or market risk as the market portfolio. Since the market risk or beta of the market portfolio is equal to one, the adjusted portfolio is constructed as a combination of the managed portfolio and risk-free asset such that the adjusted portfolio has a beta equal to one. The weights are specified as in equations below.

$$w_{r_p} = \frac{\beta_m}{\beta_p} \quad (35.10)$$

$$w_{r_f} = 1 - w_{r_p} \quad (35.11)$$

where w_{rp} represents the weight given to the managed portfolio, which is equal to the beta of the market portfolio (β_m) divided by the beta of the managed portfolio (β_p). w_{rf} is the weight on the risk-free asset and is equal to one minus the weight on the managed portfolio. The beta of the adjusted portfolio (β_p^*) is the weight on the managed portfolio times the beta of the managed portfolio, and this will be equal to the risk of the market portfolio as shown in the following equation:

$$\beta_{p*} = w_{r_p} \times \beta_p = \frac{\beta_m}{\beta_p} \times \beta_p = \beta_m \quad (35.12)$$

The return of the adjusted portfolio (r_p^*) is computed as the weighted average of the returns of the managed portfolio and the risk-free rate, where the weights are as determined above in Equations 35.10 and 35.11:

$$r_{p*} = w_{r_f} \times r_f + w_{r_p} \times r_p \quad (35.13)$$

The return on the adjusted portfolio can be readily compared with the return on the market portfolio since both have the same level of market risk. The differential return, T^2, indicates the excess return of the managed portfolio in comparison to the benchmark portfolio after adjusting for differences in the market risk.

In the example, the beta of the managed portfolio is 1.5. Hence, $w_{r_p} = 1.0/1.5 = 0.67$ and $w_{r_f} = 1 - 0.67 = 0.33$. The adjusted portfolio would be 67% invested in the managed portfolio and 33% invested in Treasury bills. The beta of the adjusted portfolio, $\sigma_p^* = 0.67 \times 1.5 = 1.00$, which is equal to the beta of the market portfolio. The return on the adjusted portfolio would be $r_p^* = 0.33 \times 4\% + 0.67 \times 20\% = 14.72\%$. $T^2 = 14.72 - 13.00\% = 1.72\%$. Thus, after adjusting for market risk, the managed portfolio has

performed better than the benchmark by 1.72%. T^2 is a better measure of relative performance when the market risk of a managed portfolio is the relevant risk metric.

Call Auction Trading[1]

36

Robert A. Schwartz and Reto Francioni

Abstract

A call auction is an order driven facility which, in contrast with continuous trading, batches multiple orders together for simultaneous execution in a multilateral trade, at a single price, at a predetermined point in time, by a predetermined matching algorithm. The chapter describes how orders are handled and clearing prices set in call auction trading, contrasts call auctions with continuous trading, and identifies different types of call auctions (including price scan auctions, sealed bid auctions, and open limit order book auctions). Attention is given to the use of information technology in call market design, the integration of an auction in a market's micro-structure, and to the facility's ability to deal with market quality issues such as containing intra-day price volatility, sharpening price discovery, and catering to participant demands for immediacy. To produce robust results, a call auction must attract sufficient critical mass order flow; the paper concludes by noting that, because large traders in particular are reluctant to enter their orders early in the auction process, book building cannot be taken for granted.

Keywords

Book building • Continuous trading • Critical mass order flow • Hybrid markets • Information technology • Intra-day price volatility • Open limit order book auction • Order driven facility • Price and time priority • Price discovery • Price improvement • Price scan auction • Sealed bid auction

A call auction is an order driven facility that batches multiple orders together for simultaneous execution in a multilateral trade, at a single price, at a predetermined point in time. This contrasts with continuous trading where a trade can occur whenever a buy and a sell order cross in price. Our discussion of call auction trading is implicitly in the context of equity trading, but the concepts involved apply to a far greater array of financial instruments and nonfinancial resources.

The call auction form of trading died out in the precomputer age but has made its re-entrance today as an electronic marketplace. An electronic call auction has been incorporated in recent years in a number of market centers around the world, most notably Deutsche Börse, Euronext (the Paris, Amsterdam, Brussels and Lisbon, exchanges), the London Stock Exchange, and the NASDAQ Stock Market. These electronic calls are not being used as standalone systems, but have been combined with continuous trading to create hybrid markets. When it comes to trading, one size does not fit all. With a hybrid system, an investor can select among alternative trading venues depending on the size of the order, the liquidity of the stock being traded, and the investor's own motive for trading.

A pure "order driven" market is a trading environment where all of the participants are investors seeking to buy or to sell shares for their own portfolio purposes. The environment is called "order driven" because limit orders that are placed by some

[1]See note 1.

e-mail: Robert_Schwartz@baruch.cuny.edu

R. Francioni
Swiss Stock Exchange, Switzerland

participants set the prices at which others can trade by market order. Most order driven markets are not "pure," but allow for market making. Even without imposing specific obligations or offering incentives, large market participants often choose to make markets as a specific business line. There is a need for market making services, and these services get paid for.

An order driven market can be structured in two fundamentally different ways. With a "continuous" market, a trade can be made at any moment in continuous time that a buy order and a sell order meet in price. In the continuous market, trading is generally a sequence of bilateral matches. Alternatively, in a "call auction," orders are batched together for a simultaneous execution. At the time of a call, a market clearing price is determined, and buy orders at this price and higher execute, as do sell orders at this price and lower.

Call auctions and continuous trading both have their advantages and their shortcomings. In most exchanges, both methods are combined, as are order driven and quote driven facilities[2] so as to form an optimum structure for all kinds of users. In principle, an auction appears to be the ideal way of defining the equilibrium market price at a specific point in time. Continuous trading is more apt to resemble a never ending crawl around a dynamically evolving equilibrium price.

Many retail customers are accustomed to trading with immediacy. Nevertheless, if there were only retail orders, periodic calls would probably be the better way to provide fair and equitable treatment to every investor. However, markets must also cope with the problem of handling big block orders. A lot of interaction with the market is needed to trade large orders. That is where some see the advantage of continuous trading. It offers a special kind of interaction between the market participants, opportunities to test the market, and to get information from the market. For big orders, periodic calls may not provide the kind of flexibility that some participants want.

On both sides of the Atlantic, this has led to combinations of both call and continuous systems. Call auctions are typically used at the beginning of each trading session to open their continuous order driven markets. The opening price has special importance because orders that have come in during the overnight trading halt are normally considered to have an equal right to get filled, at least partly, at the opening price. Setting the opening price should, therefore, be done carefully – be it by a well-structured auction or through a less formalized process. Calls can also be used to close the market. The major European equity markets and NASDAQ in the United States do this to sharpen the accuracy of price determination at this critical time of the trading day, and in recognition of the multiplicity of uses to which the closing prices are put (at index rebalancings and derivative expirations, as well as for marking-to-market in derivative markets, share valuations for various other legal purposes, etc.). Some exchanges also run periodic calls during a trading session (Deutsche Börse's market model includes one intra-day call). The intra-day calls are important particularly for securities with low trading volume.

36.1 Order Handling

Orders are handled differently in call auctions than in continuous trading, and the time clock is used differently. With a call auction, trades are made at specific points in time rather than whenever, in continuous time, a buy and a sell order cross. To accomplish this, orders submitted to a call auction that could otherwise have been matched and executed are batched together for a multilateral clearing. The clearings are – generally held at predetermined points in time (at the open, at the close, and/or at set times during the trading day).

As noted, at the time of a call, the batched orders are matched, and a single clearing price is established. The single clearing price reflects the full set of orders submitted to the call. Buy orders at this value and higher execute, as do sell orders at this value and lower. Because all executed orders clear at the same price, there is no bid–ask spread in call auction trading. Further, with single price clearing, buy orders priced above the single clearing value and sell orders priced below it receive price improvement.

36.2 Alternative Call Auction Designs

Many variations in auction design exist. Calls can be held "on request" instead of at predetermined regular intervals. Multiple (discriminatory) pricing in a call is possible. The amount of precall pricing information to reveal is a decision variable. Traders may be free to change their orders/quotes quotes until the last moment, or there may be restrictions of various kinds. And so forth.

Taking an aerial view, we identify four basic types of call auctions (with several variations in between).

36.2.1 Price Scan Auctions

In a price scan auction, a sequence of prices is "called out" until a value is found that best balances the buy and sell orders. The NYSE call auction opening best fits into this category. The exchange specialists periodically announce indicated opening price ranges, traders respond with their orders, and as they do, the specialists adjust their indicated opening prices.[3]

36.2.2 Sealed Bid Auctions

In a sealed bid auction, participants submit their orders in sealed envelopes that are not opened until the time of the auction. These auctions are totally "closed book" (non-transparent) during the preopen phase, and consequently no
Fig. 36.1 Batching of customer orders

Fig. 36.2 Cumulation of the buy orders

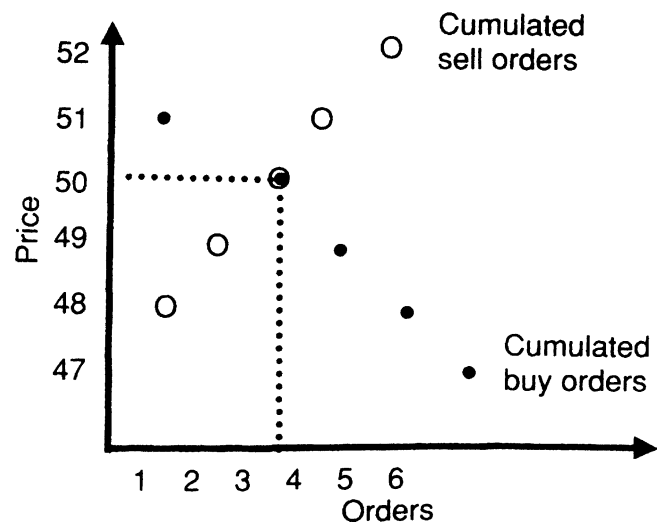
Fig. 36.3 Cumulation of the sell orders


Fig. 36.4 Matching of the cumulated buy and sell orders

participant knows what orders the others are submitting. The term may also be applied more broadly when orders are submitted electronically or by other means if pre-trade orders and indicated clearing prices are not revealed to participants. The U.S. Treasury's new issues market is a good example of the sealed bid auction.

In an electronic trading environment, the auction can be set up with various degrees of preauction transparency that allows traders to react to an indicated clearing price that is continuously displayed as the market forms. This functionality characterizes the third category of call auctions:

36.2.3 Open Limit Order Book

With an open limit order book, posted orders are displayed to the public in the precall order entry period. As the time of the call approaches, the procedure also identifies and updates an indicated clearing price, which at each instant, is the value that would be set in the call if the call were to be held at that instant. At the time of the call, the book is frozen

and the indicated clearing price becomes the actual clearing price. The open limit order book call is used in most electronic order driven trading platforms around the world.

The fourth category is not, strictly speaking, a call because it does not undertake price discovery. However, because it is based on the principle of order batching, we include it here:

36.2.4 Crossing Networks

A crossing network does not discover price. Rather, buy and sell orders are matched in a multilateral trade at a price that is set elsewhere. Generally, the value used at a cross is either the last transaction price or the midpoint of the bid–ask spread set in a major market center. In the United States, ITG's Posit crosses and Instinet's cross are good examples of this facility.

36.3 Order Batching and Price Determination

Figures 36.1, 36.2, 36.3, and 36.4 describe order batching and price determination in a call. In each of these figures, share price is shown on the vertical axis, and the number of orders is shown on the horizontal axis. The number of shares sought for purchase or offered for sale is conventionally displayed on the horizontal axis, but the exposition is simplified by assuming that all orders are for the same number of shares (e.g. one round lot). The following legend is used in the diagrams:

- Individual buy order
- Cumulative buy orders at the price or better
- Individual sell order
- Cumulative sell order at the price or better

Figure 36.1 displays the individual buy and sell orders. The horizontal axis gives the total number of orders (buys plus sells) that have been placed at each price. At each price, the orders are arrayed according to the sequence in which they have arrived. At the price of 52, just one sell order has been placed. At 51, a sell order arrived first, and then a buy order. At 50, two buy orders arrived followed by one sell order. And so on.

Figures 36.2 and 36.3 show how the individual buy and sell orders are aggregated. The buy orders only (both individual and aggregated) are shown in Figure 36.2. Because the price limit on a buy order is the highest price at which the order is to be executed, the buy orders are cumulated from the highest price (in this case 51) down to the lowest (47). At 51, there is just one order to buy. Two additional buy orders have been entered at 50, and thus at 50, there is a total of three buy orders. At yet lower prices, one order has been placed at each of the prices, 49, 48, and 47. Thus, the cumulative number of orders at these prices is four, five, and six, respectively.

The sell orders only (both individual and aggregated) are shown in Figure 36.3, and they are also cumulated. Because the price limit on a sell order is the lowest price at which the order is to be executed, the sell orders are cumulated from the lowest price (48) up to the highest price (52). There is only one sell order at each of the prices, and the cumulative number of sell orders increases by one order as we move from the single order at 48 to the five orders at 52.

The cumulative buy and sell orders are matched together in Figure 36.4 to determine the clearing price at which they execute and the specific orders that execute. At the intersection of the two curves, price is 50 and the number of orders is three. Thus, three buy orders execute (the one placed at 51 and the two at 50) and three sell orders execute (the one placed at 48, the one at 49, and the one at 50). Note that three is the maximum number of orders that can execute: at

the higher price of 51 there is only one buy order, and at the lower price of 49 there are only two sell orders. For this reason, the clearing price in a call auction is typically identified as the value that maximizes the number of shares that execute (and, in the special case presented here, the number of orders that execute).

Note that the most aggressive buy orders are matched with the most aggressive sell orders. This is because orders receive price priority. Namely, the most aggressive orders (on either side) are executed first. As we discuss below, if several orders have the same price limits, the order that was input first gets executed first (time priority). In the example depicted in Figure 36.4, three of the executed orders receive price improvement (the buy at 51, the sell at 49, and the sell at 48). The less aggressive orders (the buys at 49, 48, and 47, and the sells at 51 and 52) remain unexecuted. These orders may be rolled into the continuous market, held for the next call, or cancelled, depending on the wishes of the investor.

In Figure 36.4, at the market-clearing price of 50, the cumulated sell orders match the cumulated buy orders exactly. What if no price exists that gives an exact match? For instance, what would happen if, everything else constant, three buy orders rather than two were entered at 50? The decision rule would still pick 50 to be the price (this value would still maximize the number of orders that execute), but with a cumulative of only three sell orders at 50, only three of the four buy orders can be executed.

A further decision rule is needed to specify which three of the four orders to pick. The rule commonly used is the "time priority rule:" orders execute according to the sequence in which they were placed, with the first to arrive being the first to execute. Time priority is valuable in call auction trading as it gives participants an incentive to place their orders earlier in the precall, order entry period.[4]

36.4 Relationship Between Limit and Market Orders

Limit orders and market orders are very different order types in continuous trading, but are virtually the same in call auction trading. For continuous markets, limit orders set the prices at which market orders execute, and limit orders sitting on the book provide immediacy to the market orders (i.e. the market orders execute upon arrival). Limit order traders are willing to wait patiently for an execution and they are the liquidity providers. In a continuous market, market order traders demand immediate liquidity.

In contrast, market orders in the call environment are nothing more than extremely aggressively priced limit orders. Specifically, a market order to buy has an effective price limit of infinity and a market order to sell has an

effective price limit of zero. Participants in a call auction all wait until the next call for their orders to execute, and thus market orders in a call auction do not receive immediacy as they do in continuous trading. The distinction in continuous trading that limit order placers supply liquidity while market order placers demand liquidity, does not apply to call auction trading. In a call auction, all participants supply liquidity to each other. However, with an open book call, those participants who place their orders early in the precall order entry period are key to the book building process. As we discuss further below, early order placers are the catalysts for liquidity supply.

36.5   The Electronic Call Auction

Over 100 years ago, the New York Stock Exchange was a call market (nonelectronic, of course). In some respects, the nonelectronic call was a fine system for participants on the exchange floor but it had deficiencies for anybody away from the floor. Investors not physically present had little knowledge of what was happening (the calls offered no transparency), and access to trading was limited because shares of a stock could be exchanged only periodically (when the market for the stock was called). On May 8, 1869, the call procedure was abandoned when the NYSE merged with a competing exchange, the Open Board of Brokers, and became a continuous trading environment.

The Tel-Aviv Stock Exchange through the 1970s and the Paris Bourse before the 1986 introduction of its electronic market, CAC (the acronym stands for "*Cotation Assistée en Continu*"), were also nonelectronic call auctions that did not survive.

Call auction trading had been very popular with continental European exchanges in the earlier days when they still had floor trading. But with growing competition among exchanges, continuous trading became increasingly popular. This went hand-in-hand with extended trading hours. Both developments meant that the volume at the opening call got thinner and its importance was reduced. The widespread trend to fully automated trading of most European exchanges, however, has allowed for new solutions and combinations.

In recent years, tremendous advances in information technology and a slew of other developments in the industry have paved the way for the call's reentry. With an electronic open limit order book, participants anywhere around the globe are able to see the auction as it forms, and can enter their own orders with electronic speed. Compared to traditional floor trading, electronic trading offers new flexibilities for fine-tuning market architecture. Automated order book trading usually starts with an opening call and uses a call to resume trading after any halt. As noted, the major European exchanges and NASDAQ have also introduced closing electronic calls, particularly to provide "better" closing prices. For securities with little liquidity and less frequent trading, one or two calls per day may suffice.

While information technology (IT) can be used advantageously in continuous trading, it is essential for efficient call auction trading. Moreover, the call auction is an extremely good environment for the application of IT. In a continuous market, IT speeds up the rate at which orders can be submitted, displayed, and turned into trades, and in so doing, it accentuates the importance of nanoseconds. In an electronic call auction environment, on the other hand, IT is used to sort and cumulate orders, and to find the clearing prices. In a call auction, the computer is used to do one thing in particular that it was created to do, namely, to compute.

The electronic call auction is appealing for small and mid-cap stocks because order batching augments the efficiency of liquidity provision by focusing liquidity at specific points in time. The procedure also has particular appeal for the large cap stocks, because it caters to the needs of institutional participants whose portfolios are mostly comprised of these issues. Market impact is reduced for the institutional investor because the call is a point in time meeting place, and as noted, batching orders in a multilateral trade focuses liquidity. For all stocks, commissions may be lower due to the greater ease of handling orders and clearing trades in the call auction environment.

For the broad market, electronic call auctions can reduce short-period (e.g. intra-day) price volatility, unreliable pricing, unequal access to the market, and various forms of manipulation and abuse.[5] Further, the electronic call auction is an explicit price discovery facility. That is, batching many orders together for simultaneous execution at a single price produces a consensus value that better reflects the broad market's desire to hold shares. Consequently, the electronic call auction is a good opening facility for the continuous order driven market. Moreover, because it is an explicit price discovery facility, call auction trading can be used to dampen short-period (e.g. intra-day) price volatility.

One feature of call auction trading that has been thought by some to be a drawback is that it does not provide transactional immediacy (participants have to wait for a call). With call and continuous trading combined in a hybrid market structure, this limitation ceases to be a deficiency. And, in any event, immediacy involves a cost (bid–ask spreads and market impact costs) that not all investors wish to pay. Retail and institutional customers who place limit orders are not looking for immediate executions and many institutional customers are more concerned with anonymity and keeping trading costs low than with obtaining immediate executions.

To deliver its promise of being a highly efficient trading environment, a call auction must attract sufficient volume. To accomplish this, some order placers must be incented to

enter their orders early in the precall order entry period. The early stages of book building cannot be taken for granted, however, especially for an auction that opens the market at the start of a trading day. Some participants, particularly big institutional customers, are reluctant to post orders, an act that may reveal their trading intentions when the book is thin. Nevertheless, early order placers, the catalysts for liquidity supply, are needed. Two incentives for early order placement are (1) the use of time priorities and (2) reduced commission rates for early order entry. The inclusion of retail customers who are less concerned that their small orders will have any meaningful impact on the clearing price also helps. Lastly, a market maker could play an important role in animating book building during the precall order entry period.

Schwartz and Reto Francioni; This material is used by permission of John Wiley); and Robert A. Schwartz, (2003) "The Call Auction Alternative," In Robert A. Schwartz, John Aidan Byrne and Antoinette Colaninno (eds.) *Call Auction Trading: New Answers to Old Questions*, Kluwer Academic Publishers (Springer).

2. In a quote driven market, the quotes of a dealer or market maker establish the prices at which others can trade by market order.

3. The Paris Stock Exchange's market, before the Bourse introduced electronic trading in 1986, was a classic price scan call auction. When the market for a stock was called, an auctioneer would cry out one price after another, scanning the range of possibilities, until an acceptable balance was found between the buy and sell orders.

4. Further situations can be described that require more complex rules of order execution. As is typically the case, the set of decision rules required for an actual operating system is far more complicated than those we need consider to achieve a basic understanding of a system.

5. For further discussion of the properties of call auction trading, see Cohen and Schwartz (1989), Economides and Schwartz (1995), and Schwartz, Francioni and Weber (2006), Chapter 4.

Market Liquidity[*]

<div style="text-align:right">**37**</div>

Robert A. Schwartz and Lin Peng

Abstract

Liquidity, which is integrally related to trading costs, refers to the ability of individuals to trade at reasonable prices with reasonable speed. As such, liquidity is a major determinant, along with risk and return, of a company's share value. Unfortunately, an operational, generally accepted measure of liquidity does not exist. This entry considers the following proxy measures: the bid–ask spread, the liquidity ratio (which relates the number or value of shares traded during a brief interval to the absolute value of the percentage price change over the interval), and the variance ratio (which relates the volatility of short-term price movements to longer-term price movements). The determinants of liquidity considered are the size of the market for a stock and market structure. The paper concludes by stressing that illiquidity increases the cost of equity capital for firms, but that trading costs can be reduced and liquidity enhanced by the institution of a superior trading system.

Liquidity refers broadly to the ability of individuals to trade quickly at prices that are reasonable in light of underlying demand/supply conditions. Liquidity, risk, and return are the major determinants of a company's share value. Risk constant and expected return must be higher and a company's cost of capital greater, if the market for its shares is less liquid. A number of authors have studied the cross-sectional relationship between liquidity and asset prices (see, for example, Amihud and Mendelson, 1986; Brennan and Subrahmanyam, 1996; Easley et al., 2002; Pastor and Stambaugh, 2003), as well as the time series relationship (Jones, 2002). However, a comprehensive understanding of the impact and determinants of liquidity is still lacking. The problem is that an operational, generally accepted measure of liquidity does not exist. (Lippman and McCall, 1986)

Liquidity is often described by the depth, breadth, and resiliency of the market for an asset. A market has depth and breadth if orders exist at an array of prices in the close neighborhood above and below the values at which shares are currently trading, and if the buy and sell orders exist in substantial volume. A market is resilient if temporary price changes due to order imbalances quickly attract new orders that restore reasonable share values.

Liquidity (and its converse, illiquidity) can also be defined in terms of the transaction costs incurred to obtain a fast execution. (Beebower et al., 1985; Bernstein, 1987; Economides and Siow, 1988; Grossman and Miller, 1988) Transaction costs include an explicit component such as commissions, and an implicit component such as a bid–ask spread and market impact. The ask quotation is the price at which shares can be purchased with immediacy, and the bid quotation is the price at which shares can be sold with

immediacy. The difference, known as the bid–ask spread, is the cost of a round-trip, and half of the spread is typically viewed as the cost of buying or selling shares immediately.

Market impact exists when a buy order drives the ask up, or a sell order drives the bid down. This occurs because the volume of shares at the quotes may be small relative to the size of the order, and/or because of the dissemination of the information that a large trader has arrived in the market. The spread and market impact are large if a market lacks depth and breadth.

Bid–ask spreads are directly quantifiable, but market impact is very difficult. The problem is twofold. First, because of information leaks and front-running, an order can impact prices before it reaches the market. Second, prices are constantly changing due to news and liquidity trading, and thus a reasonable benchmark against which to assess the implicit cost components of a transaction price is not readily available.

Prices are also distorted due to the difficulty of finding equilibrium values in the marketplace. Errors in price discovery occur because prices depend on the order flow while simultaneously orders are priced with imperfect information about the underlying consensus values. Analogous to the market impact effect, transaction prices can be pushed up if impatient buyers outnumber impatient sellers, or can be pushed down if impatient sellers outnumber impatient buyers (Ho et al., 1985). In a resilient market, errors in price discovery are quickly corrected.

None of the attributes of liquidity thus far discussed provide an unambiguous measure of the concept. One commonly used measure is the bid–ask spread (Amihud and Mendelson, 1986). Another is the liquidity ratio, which relates the number or value of shares traded during a brief time interval to the absolute value of the percentage price change over the interval. The larger the ratio of shares traded to the percentage price change, the more liquid the market is presumed to be. This view underlies measures of specialist performance that have been used by various stock exchanges, and characterizes the approach taken by some researchers to measure and to contrast the liquidity of different market centers (Cooper et al., 1985; Hui and Heubel, 1984).

The liquidity ratio, however, can be misleading. If news causes prices to change, a large liquidity ratio that is attributed to heavy trading volume would suggest that prices have adjusted too slowly in response to the informational change. This is because a bid that is too high attracts market orders to sell, and an ask that is too low attracts market orders to buy. Consequently, to the extent that trading is triggered by informational change (rather than by idiosyncratic investor needs), trading volume is less, and the liquidity ratio is smaller (not larger) in a more efficient market.

Another measure of liquidity is the variance ratio, which relates the volatility of short-term price movements to the volatility of longer-term price movements. Transaction prices jump up and down as executions bounce between the bid and the ask, as large orders impact prices, and as transaction prices fluctuate around equilibrium values due to price discovery errors. Thus, implicit execution costs increase the volatility of short-term price movements. Because the effect attenuates as the interval over which price changes are measured is lengthened, it is possible to proxy liquidity by the variance ratio. Hasbrouck and Schwartz (1988), for example, find that an appropriately adjusted ratio of 2-day to ½-h returns variance is predominantly less than unity (the value expected for a perfectly liquid market) for a large sample of NYSE, Amex and OTC stocks. Ozenbas et al. (2002) report an accentuation of intra-day volatility that is most pronounced in the first half-hour of a trading day in five markets – the New York Stock Exchange and NASDAQ in the United States, and the London Stock Exchange, Euronext Paris and Deutsche Börse in Europe.

A primary determinant of liquidity is the size of the market for a stock (or inversely, thinness). Size can be measured as the number or value of shares outstanding, the number or value of shares traded, and/or the number of shareholders. Empirical studies have shown that spreads are wider, market impact greater, and price discovery less accurate for thinner issues (Cohen et al., 1986; Schwartz and Francioni, 2004). But even for larger issues, markets can be thin, particularly for big, institutional investors. This is because, during any trading session, only a relatively small number of individuals actually seek to trade. For small-cap and mid-cap stocks, the problem may be particularly striking within a trading day: at any given moment, only a handful of individuals (if any) may be actively looking to buy or to sell shares.

Market structure also affects the liquidity of individual issues, and the U.S. Securities and Exchange Commission has required that execution venues report their execution quality on multiple dimensions (see SEC, 2000). The primary market makers in certain market centers are dealers and specialists, whose role is to supply immediacy to public traders. In this context, the provision of immediacy is essentially synonymous with the provision of liquidity, the ability to transact quickly at reasonable prices. Liquidity may also be enhanced by other market structure mechanisms. One important approach would be to increase the depth and breadth of a market by encouraging public traders to place more limit orders. The imposition of rules to prevent destabilizing trades (i.e. tick-test rules) and the time bunching of orders are two other ways to increase liquidity. In 2001, the NYSE and NASDAQ completed a conversion from fractional to decimal prices under pressure from the SEC. The switch has resulted in sharply reduced quoted spreads. However, there is evidence that the inside market depth has been reduced for the large traders (Sofianos, 2001).

Public orders generally execute at inferior prices in illiquid markets. As a consequence, expected returns on securities traded in less liquid markets must be higher and the cost of capital for the listed companies is greater. The important insight is that the costs of trading can be decreased by the institution of a superior trading system. In the limit, as a market becomes frictionless, the issues traded in it become perfectly liquid.

Market Makers[*]

38

Robert A. Schwartz and Lin Peng

Abstract

The primary focus of this entry is on market maker services, revenues, and costs. A market maker's basic function is to service the public's demand to trade with immediacy by continuously standing ready to buy shares from customers who wish to sell, and to sell shares to customers who wish to buy. Additionally, the market maker helps to stabilize prices and to facilitate a reasonably accurate price discovery. Further, a special type of market maker – a stock exchange specialist – fulfills the role of an auctioneer. The bid–ask spread is the classic source of market maker profits, while the costs of market maker operations include: order-processing, risk-bearing (the cost of carrying an unbalanced portfolio), and adverse selection (the cost of trading with a better-informed participant). The paper further considers the competitive environment that market makers operate within, and concludes with the thought that institutionalization, the advent of electronic trading, deregulation, and globalization of the equity markets have led to major changes in market maker operations in the recent past, and will continue to do so in the coming years.

Market makers play a central role in many equity markets by buying and selling shares to service the public's demand to trade immediately (the classic service provided by a dealer). Market makers are also responsible for stabilizing prices (making a market "fair and orderly") and facilitating price determination. Some market makers, such as stock exchange specialists, also perform the role of auctioneer.

Demsetz (1968) was one of the first to analyze the supply of immediacy. Buyers and sellers arrive sporadically at the market, and it is not a simple matter for them to find each other in time. The market maker provides a solution by continuously standing ready to trade from his or her own inventory of shares. The service is not free, however. The dealer sells to buyers at higher ask prices, and buys from sellers at lower bid prices. The bid–ask spread is the market maker's compensation (sometimes referred to as "the dealer's turn").

Market makers are not necessary for immediacy to be provided to a market. Public traders can post limit orders with commission brokers acting as middlemen. However, immediacy is not the only marketability service provided by a market maker.

R.A. Schwartz (✉) • L. Peng
Baruch College of the City University of New York, NY, USA
e-mail: Robert_Schwartz@baruch.cuny.edu

The liquidity provided by market makers also helps to stabilize prices. Most participants in the securities markets prefer prices that, all else equal, are less volatile. They care about this as investors because they are generally assumed to be risk-averse. They care about this as traders because they are averse to transaction price uncertainty. Market maker intervention helps to stabilize price fluctuations in the short run. The U.S. exchange specialist in particular has an "affirmative obligation" to make a fair and orderly market.

Market makers also facilitate the determination of accurate prices. First, their own quotes directly set market prices. Second, their quotes are signals that public traders react to in writing their orders; therefore, market makers indirectly affect market prices by influencing the public order flow. Third, exchange specialists establish market-clearing prices at the opening of the trading day and at the resumption of trading after halts caused by the advent of news.

Price stabilization and price discovery are both consistent with the provision of immediacy. This is because "immediacy" means not only the ability to trade promptly, but also the ability to trade in reasonable amounts at prices that properly reflect current market conditions. (Smidt, 1971 emphasizes the supply of liquidity in depth, namely the ability of investors to trade quickly and in size, at the market maker's quotes.) Consequently, transactional immediacy, price stability and accurate price discovery are all attributes of markets that are "fair and orderly."

As auctioneers in an agency market, market makers also organize and oversee trading. Stock exchange specialists do so by maintaining the limit order books and by assuring that trading rules are not violated. On some exchanges (such as the Tokyo Stock Exchange), market makers act only in the clerical bookkeeping and regulatory oversight capacities, and are not allowed to trade the stocks assigned to them.

The bid–ask spread set by the market maker reflects the following components: order-processing costs, risk premium or inventory costs, adverse selection costs, and profit (Stoll, 1989). The order-processing costs compensate market makers for their time and effort, cost of paper-work, etc. Risk bearing is central to the dealership function (Amihud and Mendelson, 1980; Ho and Stoll, 1981). The market maker trades to make a market rather than for his or her own investment motives. If buyers appear, a market maker must be willing to assume a short position; if sellers arrive, the market maker must be willing to assume a long position. As a result, the market maker generally acquires an unbalanced portfolio. The market maker is then subject to uncertainty concerning the future price and the future transactions volume in the asset. Not knowing when transactions will be made, the market maker does not know for how long an unbalanced inventory position will have to be maintained. An unbalanced inventory position implies the existence of diversifiable risk. Thus, the market maker requires a risk premium on the inventory risk, which other investors can eliminate by proper portfolio diversification (the expected return on a stock compensates all investors and market makers for accepting nondiversifiable risk).

Market makers also protect themselves against adverse selection. Public orders to purchase or to sell securities are motivated by either idiosyncratic liquidity reasons or informational change. The market maker typically does not know whether an order has originated from an informed trader or from a liquidity trader. If a public trader receives news and transmits the order before the market maker has learned of the informational change, the public trader profits at the market maker's expense (Bagehot, 1971; Copeland and Galai, 1983; Glosten and Milgrom, 1985). The market maker responds to the cost of ignorance by increasing the ask quote and lowering the bid so that the expected loss to the informed traders is compensated by the expected gain from the liquidity traders. The market maker cannot achieve total protection, however, by sufficiently widening the spread. Regardless of how much the offer is raised and/or or the bid is lowered, any informationally motivated trade would be at the market maker's expense.

And the defensive maneuver is not costless. The market maker profits from liquidity trades, and in the process of widening the spread to guard against informed traders, increases the cost of transacting and so loses an increasing number of liquidity traders. Yet, there must be investors who trade for noninformational reasons. Without the liquidity traders, the dealer market would collapse (Grossman and Stiglitz, 1980).

The competitive environment of a market maker firm differs depending on whether it operates in an agency/auction environment or in a dealer market. In an agency/auction market, limit order traders and floor traders provide competition for the single market maker (stock exchange specialist). In contrast, a dealer market is competitive only if the order flow for a security is directed to more than one dealer firm. This competition for market-ability services fragments the informational content of the order flow, however. In other words, each dealer firm knows what buy and sell orders it receives, but does not observe the flow of orders to competing dealer firms. However, in a screen-based system, each dealer firm does see the quotes posted by others. In addition, information is transferred by transaction price reporting and via inter-dealer trading.

The online reporting of large transactions, however, can signal information about a dealer's inventory position to its competitors. And, when the order flow is dominated by institutional investors, as on the London Stock Exchange, other problems can arise (see Neuberger and Schwartz, 1990). These include fair-weather market making (taking the privileges but failing to meet the obligations of market making), preferencing (the diversion of order flow to a market maker firm that is not necessarily posting the best quotes, but that has guaranteed best-price execution

nonetheless), handling a lumpy order flow (few trades but of large size), and coping with one-way markets (buyers only or sellers only). All told, market making is a complex, multifaceted operation.

Institutionalization, the advent of electronic trading, deregulation, and globalization of the equity markets are having a profound impact on securities trading and price determination. These forces have led to major changes in market maker operations in the recent past, and will continue to do so in the coming years.

Structure of Securities Markets[*]

39

Robert A. Schwartz and Lin Peng

Abstract

The entry reviews essential elements of market structure – the systems, procedures, and protocols that determine how orders are handled, translated into trades, and transaction prices determined. There are various contrasting alternatives, such as order-driven and quote-driven markets; consolidated vs fragmented markets; human intervention vs electronic trading; and continuous markets vs periodic call auctions. A major objective of market design noted in the discussion is to enhance the accuracy with which prices are discovered in a dynamic, uncertain environment. Lastly, the entry points out that market structures are rapidly changing, and that much remains to be learned about how best to structure a technologically sophisticated, hybrid market that efficiently services the varied needs of diverse participants.

The structure of a securities market refers to the systems, procedures, and protocols that determine how orders are handled, translated into trades, and transaction prices determined. To date, theoretical security valuation models have generally not considered the effect of a market's structure on asset prices. Formulations such as the Capital Asset Pricing Model and the Arbitrage Pricing Theory, for example, address the risk and return dimensions of a security, but ignore considerations such as liquidity, trading costs, information costs, and transaction uncertainty. When these realities are taken into account, it is apparent that market structure matters, that it does affect the price and size of trades.

Market structures differ significantly among major international equity market centers (see Schwartz and Francioni, 2004). The New York Stock Exchange (NYSE) and other U.S. stock exchanges are agency/auction markets where the market maker (specialist) acts as both dealer and broker's broker. Examples of a dealer market include the Nasdaq market in the United States and the London Stock Exchange (LSE) before they introduced their electronic order-driven trading systems (Supermontage for Nasdaq and SETS for the LSE). The Tokyo Stock Exchange (TSE) is an agency/auction market where the market maker (saitori) handles the orders but does not take a dealership position. Markets also differ in the way in which orders are consolidated or fragmented, in the way in which information is disseminated, and in the degree to which trading is computerized.

Whether investors trade through an intermediary, as in a dealer market, or directly with each other, as in an agency/auction market, is one of the most important

R.A. Schwartz (✉) • L. Peng

NY, USA
e-mail: Robert_Schwartz@baruch.cuny.edu

distinctions in market structure. In a dealer market, the market maker initiates trades by posting bid and ask quotations that are publicly disseminated. The bid is the price at which public traders can sell to a dealer, and the ask is the price at which they can buy from a dealer. The bid–ask spread is the dealer's compensation for providing marketability services. To achieve a trade in a dealer market, a customer (usually via a broker) contacts a dealer by telephone or electronically and accepts his or her quotation.

In an agency/auction market, public participants trade with each other, and floor professionals in an agency market such as the NYSE act in a brokerage (agency) capacity. When trading is active in a stock, floor traders gather in a "crowd," and trading truly takes place in an auction environment. In the U.S. exchanges, orders are consolidated at the posts of specialists, who are market professionals who function as both principals and as agents. Specialists have an affirmative obligation to buy and to sell shares so as to make "a fair and orderly market" when counterpart orders do not provide sufficient liquidity. They also have a negative obligation: when a public order and a specialist's quote are at the same price, the specialist must step aside and let the public order execute first.

Two types of orders are commonly used in an agency/auction market: limit orders and market orders. A limit order states the maximum price at which a public investor is willing to *buy*, or the minimum price at which the public investor is willing to *sell*, a specified number of shares. A market order is unpriced; it states the number of shares the investor wishes to trade "at market," namely the price prevailing when the order is received by the market center. To execute a market order, limit orders must exist; for limit orders to exist, there must be a facility for maintaining public orders in a file (limit order book). This file characterizes agency/auction exchanges. Handa and Schwartz (1996) have examined the costs and returns to placing limit orders.

Trades may also be negotiated if they are difficult to handle because of their size. In an agency/auction environment such as the NYSE, a buyer or seller may give a not held (NH) order to a floor trader who uses his or her discretion to negotiate with other floor traders or to expose the order to the limit order book. The floor trader is "not held to the price" if the order executes at a price inferior to that which existed at the time of its arrival. Large orders are also negotiated in the "upstairs market," a network of trading desks of securities dealers and institutional investors who bring buyers and sellers together at mutually acceptable prices. Trades may also be negotiated with a dealer and/or electronically through a facility such as Liquidnet or Pipeline. Institutional investors commonly negotiate with the market makers to obtain larger sizes than the market makers are quoting and/or prices that are within the bid–ask spread. Large orders are also commonly broken up (sliced and

diced) and brought to the market in smaller tranches for execution over an extended period of time.

A major function of a market center is to find the prices at which shares are traded. This process is known as "price discovery." The accuracy of price discovery depends on the systems used for handling orders, disseminating information, and making trades. If an issue is traded in more than one market center, intermarket linkages including information systems and arbitrage operations must be implemented to ensure both adequate price protection for investors and price consistency across markets. Intermarket linkages also connect equity markets and derivative product markets (for example, the futures and options markets for stock indices in Chicago and the cash market for shares in New York).

Another feature of market structure is the means by which information concerning current market conditions (floor information) is transferred among participants. The informational signal transmitted by a quote differs significantly from that transmitted by a transaction price. A quote reflects an individual's willingness to trade; it is firm only up to its stated size and may be improved on in terms of price and/or quantity. Quotes may also reflect trading strategy and gaming by market participants. A transaction price has actually been accepted by both counterparties to a trade, but relates to the past and does not necessarily represent the price at which one can trade in the present. Nonetheless, latest transaction prices do reflect current market conditions when transactions occur frequently. For this reason, transaction price reporting has been introduced in both the U.S. and London dealer markets (see Seguin, 1991).

The extent to which orders are fragmented or consolidated in trading also defines a market's structure (see Cohen et al., 1986). A competitive dealer market is naturally fragmented in the sense that orders are routed to one of several dealer firms. This may be desirable because of the competition for marketability services that fragmentation implies. Most apparent is that bid–ask spreads are tightened in a competitive dealer environment compared to a monopoly dealer environment (see Ho and Stoll, 1983). However, given the fragmented nature of a dealer market, dealers may not be as closely regulated as the specialists in the agency/auction market. This may create incentives for dealers to collude (see Christie and Schultz, 1994a, Christie et al., 1994b). In 1996, the justice department settled with the Nasdaq dealers on accusations of spread collusion.

Another problem of the dealer market is that fragmenting the order flow across different dealer firms can obscure information and impair the accuracy of price determination (see Neuberger and Schwartz, 1990). However, in a screen-based system such as the US Nasdaq market, each dealer firm does see the quotes posted by the others. A dealer market with fragmented orders may also reduce the opportunity for the interaction of all buying and selling interest in

that security and thus reduce price competition. In 1997, the U.S. Securities and Exchange Commission enacted the Order-Handling Rules (OHRs), which required that public limit orders be exposed in the national best bid and offer (NBBO) (US Securities and Exchange Commission (SEC), 2000). The rules set in motion the transition of the Nasdaq market from a predominantly quote-driven, dealer market towards an order-driven, agency market.

Order flow in an agency/auction environment is by its nature more consolidated than in a competitive dealer market. Consolidation is desirable because it allows orders to be matched against each other with a minimum of broker–dealer intervention. Furthermore, the consolidation of orders facilitates the enforcement of order exposure and trading priority rules. The primary priority rule is price; highest-priced bids and lowest-priced asks have precedence. A secondary priority rule specifies the sequence in which orders at the same price execute; usually, the first order entered at the price is the first to execute (time priority). However, too much consolidation may lead to monopoly power for a single market center, which may lead it to lose its incentive to reduce transaction costs and to innovate.

An agency/auction market is fragmented when shares are listed on more than one exchange, traded in-house by a brokerage firm, on an Alternative Trading System (ATS) and/or on an Electronic Communications Network (ECN). This fragmentation may be desirable if it truly represents competition between market centers. It is not desirable if one market center free-rides on the prices discovered by another market center. For example, a satellite market may guarantee trades at the best price quoted in a major market center and charge lower commissions for the service.

Order consolidation facilitates the consolidation and transference of floor information. For example, NYSE specialists are in a unique position from which to observe the order flow and to set prices that are reasonable given the current demand for shares. But, like the saitori in Tokyo, specialists are not permitted to receive orders directly from customers, which restricts their access to information. In contrast, both dealers can receive orders directly from customers, including institutional traders. This contact enables them to obtain further information about market conditions.

In addition to being spatially (geographically) consolidated, orders can be consolidated temporally (over time). Orders are temporally consolidated when they are bunched together in call auction trading. In continuous trading, orders are executed whenever they cross during trading hours and, in a continuous market, trades are generally bilateral. In contrast, in call auction trading, orders are stored for simultaneous execution in multilateral trades at predetermined times when the market is "called."

Call market trading has certain advantages (see Schwartz and Francioni, 2004). In particular, dependence on the intermediation of dealers and brokers is lessened and trading costs are reduced. Since everyone trades at the same price, at the same time and under the same conditions, call market trading is fairer, and the procedure can produce prices that are more accurate and less volatile. But, traditional call market trading has had its limitations. Accessibility to the market was restricted and the dissemination of floor information poor in the old call markets of Europe. These limitations can be overcome with the use of computer technology. Pagano and Schwartz (2003) have found that the introduction of electronic call auctions at market closings on the Paris Bourse (now Euronext Paris) reduced transaction costs and improved price discovery.

One of the more striking changes in market structure that occurred as the twentieth century drew to a close was the advent of electronic trading. At its inception, electronic systems tended to mimic existing systems; now they are more commonly developing their own distinctive functionality. The first electronic exchange, the Computer Assisted Trading System (CATS), was introduced by the Toronto Stock Exchange in 1977. CATS is based on the principle of continuous trading in an agency/auction environment. The success of CATS has led to the implementation of similar systems in Tokyo (1982), Paris (1986), and elsewhere. Small order execution systems were also introduced in the U.S. and London dealer markets in the 1980s. Now most national equity markets around the globe provide floorless, electronic trading platforms. The major exceptions, the New York Stock Exchange in the U.S., is in the process of converting to a hybrid structure that integrates an electronic platform (Direct+) with its trading floor.

Electronic technology has strong advantages: it gives participants direct access to markets and control over their orders regardless of geographic location; it provides direct access to information concerning current market conditions; it provides anonymity; it enables the investors to trade without a broker and thus reduce transaction costs; and, as systems become increasingly sophisticated, the computational power of the computer facilitates the handling of institutional-sized orders and the negotiation of trades. Investors in the 1990s have witnessed a proliferation of fourth-market organizations. Electronic facilities such as Instinet and Archipelago allow members to post orders and to match that of other traders in the system. Crossing systems such as Posit and Instinet's Crossing Network allow investors to trade portfolios directly without a bid–ask spread. Liquidnet and Pipeline allow participants to find each other on their screen and negotiate their trades electronically.

Electronic technology solves the major problems associated with call market trading: restricted accessibility to a market and inadequate dissemination of floor

information (see Pagano and Schwartz, 2003). Reciprocally, a call market environment may be more suitable than the continuous market for the use of electronic technology. In particular, the submission and handling of institutional-sized orders can be accommodated in an electronic call (see Schwartz and Francioni, 2004).

Because of strong vested interests, technological inertia, and the ability of an established market center to retain order flow, the superiority of a new system may not ensure its acceptance. Market structure has evolved slowly in the United States since trading moved from coffee houses and curbs into exchanges (the American Stock Exchange did not move indoors until 1921). The pace of change accelerated in the mid-1970s with the passage of the U.S. Securities Acts Amendments of 1975, which precluded fixed commissions and mandated the development of a national market system. London's Big Bang in 1986 also precluded fixed commissions, broadened competition between dealers and brokers, and further spurred the globalization of trading. More recently, the NYSE and Nasdaq have completed a conversion from fractional to decimal prices under the pressure of the SEC. Technological developments, inter-market competition, and regulation will no doubt continue to reshape securities markets around the world. However, achieving meaningful change in market structure is not an easy task; much remains to be learned about how best to structure a technologically sophisticated, hybrid market that efficiently services the varied needs of diverse participants.

Accounting Scandals and Implications for Directors: Lessons from Enron

40

Pearl Tan and Gillian Yeo

Abstract

We analyze the Enron case to identify the risk factors that potentially led to its collapse and specific issues relating to its aggressive accounting and high-light the lessons for independent directors. In Enron, the interactions between external stimuli, strategies, corporate culture, and risk exposures possibly created an explosive situation that eventually led to its demise. Much of the post-Enron reforms have been directed towards regulating the roles and responsibilities of executive directors and auditors. However, the role of independent directors has received relatively lesser attention. Independent directors should analyze the risks of their companies and understand the pressures that arise from market conditions and firm-specific policies and incentive structures. They also need to close the information gap between executive directors and themselves. A post-Enron era also requires independent directors to change their focus. Traditionally, independent directors have to strike a difficult balance between maximizing returns and minimizing risks. Independent directors may now have to focus on the management of risks, the design and functioning of an effective corporate governance infrastructure, and the moderation of the power bases of dominant executives. Practically, they may also have to reduce the number of independent director appointments to enable them to focus more effectively on a fewer companies.

40.1 Introduction

The recent spate of accounting scandals raises serious concerns about the opportunistic use of accounting procedures and policies to camouflage fundamental problems in companies. The series of corporate collapses also high-light the failure of corporate governance mechanisms to prevent and detect accounting irregularities. The convergence of several factors, including competitive pressures, conflicts of interest, lack of market discipline, and inherent limitations of accounting standards resulted in an explosive situation whereby managers use aggressive accounting practices to present financial statements that do not reflect economic reality. In this essay, we analyze the Enron case with the objective of determining the risk factors that potentially led to its collapse and specific issues relating to its aggressive accounting and highlight the lessons to be learnt for corporate governance from the perspective of an independent director.

40.2 The Competitive Environment and Incentives for Aggressive Accounting

Enron was formed as a result of merger of two companies in 1985. The merger was funded by debt and pressure had existed from the start for the new company to reduce its debt burden. At about the same time, deregulation of the natural energy industry exposed Enron to substantial operating and price risks arising from the increase in gas supply and volatility in spot prices. However, deregulation also increased opportunities for more flexible and innovative contracts to be drawn up between the producer and buyers. To survive, Enron had to capitalize on these opportunities and became a primary market player through its development of the idea of a Gas Bank. Under this scheme, Enron facilitated the market for energy contracts by buying gas from suppliers and selling to buyers. In acting as an intermediary, Enron guaranteed both the supply and the price, and assumed the related risks in return for transaction fees. Innovations were subsequently extended to markets for basic metals, pulp and paper, and broadband products. Its diversification strategy also included investments in other countries in South America, Europe, and Asia. The business and geographical diversification created new risks for Enron. Its heavy investment in projects such as broadband network assets would pay off only in the long term. However, an immediate debt burden from these acquisitions placed pressure on Enron's balance sheet that was already weighed down by existing debt (Powers et al., 2002).[1]

Although Enron began as an operator of energy-related assets, by the end of the 1990s, the firm had divested a significant portion of its physical assets in what is known as an "asset light strategy" (Permanent Subcommittee on Investigations of the Committee of Governmental Affairs, 2002)[2] and was primarily focused on its trading and financial activities relating to physical energy commodities. Effectively, the company was transformed from a natural gas supplier into an energy trader and intermediary. It offered specialist services in price risk management strategies and market-making activities. Its dominance in the market for energy contracts gave Enron a first-mover advantage in exploiting information economies of scale. However, the lucrative profits it enjoyed attracted other entrants to the industry and Enron's profit margins began to erode by the end of 2000. Further, as a trader, Enron was compelled to maintain an investment grade rating in order to lower its counter-party risk.

Against this backdrop of competitive pressures, Enron's senior management developed incentive schemes that turned the firm environment into a highly competitive internal market place. An internal ranking system administered by the company's Performance Review Committee became a means of allocating bonus points and determining dismissals. The entire process was described as a "blood sport" (Chaffin and Fidler, 2002) and former employees believed that the basis for reward was largely determined by whether a deal could be reported as revenue or earnings rather than commitment to the company's core values of Respect, Integrity, Communication, and Excellence. Enron's annual incentive awards and the long-term incentive grants are closely tied to company performance measures and stock prices. The annual incentive bonus was pegged to a percentage of recurring after-tax profit, while its long-term incentive grants provided for accelerated vesting provided Enron achieved performance targets linked to compounded growth in earnings-per-share and cumulative shareholder returns.[3] A Senate report on the Enron collapse concluded that Enron's Board of Directors approved lavish and excessive executive compensation and failed to stem the "cumulative cash drain" arising from its incentive schemes.[4]

Hence, Enron appeared to react to risk by creating an environment that generated new risk exposures through its business strategies and reward system that focused on short-term results. Figure 40.1 summarizes the competitive pressures at Enron.

40.3 Aggressive Accounting Practices

Enron's accounting practices resulted in removing the liabilities of its balance sheet, improving profitability, and reducing profit volatility. These desired accounting effects were achieved through structuring numerous complex and "innovative" transactions. Many of these transactions involved dealing with special purpose entities that Enron set up in partnership with related parties. The investigating Senate Committee described these practices as "high-risk accounting." The manner in which certain transactions were reported was deemed to be at variance with their true economic substance. The main question that underlies these practices relates to the issue of whether Enron had retained the risks that were purportedly transferred to the special purpose entities.

40.3.1 Effectiveness of "Hedging" Transactions

An example included the entering into transactions that were purported to hedge the volatility of its "marked to market" investments. The hedging transactions were entered into between Enron and a special purpose entity (SPE).[5] A hedge is effective only if a loss suffered by a hedged party is transferred out to an outside party. In its first hedging transaction, Enron transferred its own stock to the SPE in exchange for a note. The intention of the hedge was to

Fig. 40.1 Competitive pressures at Enron
transfer losses to the SPE, through the exercise of an option, should the stock price of a profitable "merchant" investment decline. The SPE purported to take on the risk of price volatility of the investment and to compensate Enron for the loss on its investments.

However, cash was available to the SPE only if the latter sold the Enron stock. Since the SPE was financed by Enron's stock, the transaction was effectively a self-hedging arrangement as the creditworthiness of the SPE was tied to Enron's fortunes. When Enron's stock fell in value in late 2000 and early 2001, the SPE faced a liquidity crisis and could not honor its obligations under the option. Hence, the "hedge" was ineffective because the counter-party's risk was inextricably intertwined with Enron's risk and the hedge did not constitute a true economic hedge.

40.3.2 Control and Risks Relating to Unconsolidated Entities

There are two broad approaches in accounting for an SPE. If an SPE is controlled by an investing company, the assets and liabilities of the SPE are consolidated entirely on to the investing company's balance sheet. Alternatively, if it is not under the investing company's control, it is treated as an investment in a separate entity, with off-balance sheet treatment of the SPE's assets and liabilities. Under applicable accounting rules in the United States, an

SPE could receive off-balance-sheet treatment only if independent third-party investors contributed at least 3 % of the SPE's capital. Some of Enron's dealings raised serious questions about whether this rule was effectively met.

For example, from 1997 to 2001, Enron did not consolidate an SPE called Chewco. In 1997, Enron and the California Public Employees' Retirement System (CalPERS) were joint venture partners in an off-balance sheet investment vehicle called Joint Energy Development Limited Partnership (JEDI). To enable CalPERS to cash out its investment in JEDI in order to invest in a larger Enron venture, Andrew Fastow, the then Chief Financial Officer at Enron, and others at Enron formed an SPE called Chewco to buy CalPERS' interest in JEDI. Thus, Enron was able to continue accounting for JEDI as an off-balance-sheet entity on the basis that the holdings by Enron staff members and related parties constitute outside capital at risk. According to SEC investigations,[6] Fastow, secretly controlled Chewco. Hence, a serious question arose as to whether Enron, through a related party, had effective control over major operating and financial policies of Chewco. Further, Enron and its related SPEs provided guarantees and cash collateral on bank funding to Chewco, indicating that equity at risk was effectively borne by Enron rather than independent third parties. In November 2001, both Enron and its auditors, Andersen, concluded that Chewco was an SPE without sufficient

outside equity and should have been consolidated. The retroactive consolidation of Chewco from 1997 to 2001 had an astounding effect on the financial statements. Profits decreased by a total of $405 million over the period of restatement and additional debt of $711 million was recognized on the balance sheet in 1997.[7]

40.4 The Role of Corporate Governance

Theoretically, Enron had in place an impressive array of corporate governance mechanisms. Outside directors were well respected and highly qualified individuals in the fields of accounting, finance, and law. The Board of Directors had several committees to review various aspects of the company's policies and operations. There was separation of the offices of the Chairman and Chief Executive Officer. The external auditors were a Big Five accounting firm. However, following the company's massive financial collapse, serious doubts arose as to the effectiveness of these institutional arrangements. The Senate Investigating Committee found that the Enron's Board failed to safeguard Enron shareholders and contributed to the collapse of the company by allowing Enron to engage in high-risk accounting, inappropriate conflict of interest transactions, extensive undisclosed off-balance-sheet activities, and excessive executive compensation.[8] Further, the Board was also found to have failed to ensure the independence of the company's external auditor, Andersen who provided internal audit and consulting services as well.[9]

Many valuable lessons can be learnt from the Enron case to prevent the derailing of the effective functioning of governance mechanisms. We focus our discussion on the role of independent directors. Much of the post-Enron reforms have been directed towards regulating the roles and responsibilities of executive directors and auditors. However, the role of independent directors has received relatively less attention than that of other corporate governance agents. We discuss below some implications of the Enron collapse on the role of independent directors.

1. What is the primary role of independent directors? The multiple roles that independent directors have to undertake require them to strike a difficult balance between maximizing returns and minimizing risks. Their purview is wide, ranging from activities that have a "profit" focus to others that have a "defensive" focus. Independent directors potentially find themselves in an identity crisis. For example, if an independent director has to operate within an Enron-type environment, the director is confronted with an aggressive risk-taking internal environment. The question arises as to whether the independent director should act as a thorn in the managers' flesh or go with the flow of an aggressive managerial style for the sake of profit maximization?

   The lesson from Enron is very clear that it does not pay to sacrifice the defensive role when risk factors are overwhelming and the long-run survival of the company is at stake. While post-Enron legislation such as the Sarbanes–Oxley Act of 2002 is primarily directed towards establishing mandates for insiders, audit committee board members and external auditors, much less is said about the responsibilities of independent directors per se. However, the implicit responsibilities of independent directors are clearly reinforced by laws that impose fiduciary duties on directors to act in good faith, with reasonable care, and in the best interest of the corporation and its shareholders. The Conference Board also reiterates directors' role to monitor management and to ensure their ethical and legal compliance (The Conference Board, 2003).[10]

   Hence, independent directors owe a primary duty of care to outside investors. Their priority should be towards establishing and ensuring a corporate environment and infrastructure wherein managerial stewardship is executed without compromising the long-run interests of the firm and its stakeholders. They, more than anyone else, are best placed to limit the excesses of a dominant Chief Executive.

2. Independent directors have to bridge the information gap between executive directors and themselves. The Conference Board emphasizes that directors need to understand, among other things, the business strategies they approve, the risks and vulnerabilities arising from the strategies, growth opportunities, debt levels, and company's capital allocation of the companies under their purview.[11] Following the Enron experience, independent directors are well advised to understand the internal dynamics, managerial incentives, and power bases within the corporate environment and to adopt a healthy skepticism of strategies that potentially advance managerial interests over that of external investors. They should be keenly aware of the threats posed by dominant Chief Executive Officers and key personnel and the risks of opportunistic managerial behaviour.

3. Greater commitment in terms of time and effort are expected of independent directors to meet the governance objective. Independent directors must take a proactive role in governance and not rely solely on external auditors, legal counsel, or key executives to provide them the necessary assurance. For example, when the Enron Board was asked why they moved so quickly in their approval of an unusual hedging transaction, the response was that the company had obtained a fairness opinion from an outside accounting firm.[12] On another proposal, the Board relied on the company's legal counsel

to advise if anything was amiss on a particular memorandum. Had the directors reviewed the memorandum for themselves, they would have noted that key company executives were involved in the arrangement that gave rise to conflicts of interest.[13] Interviewed Board members told the investigating Senate Subcommittee members that they assumed that the then Chief Executive Officer had actively reviewed and approved the fairness of the unusual business proposals and the compensation controls.[14] Enron's directors were also found to have knowingly allowed Enron's use of "high-risk" accounting without enforcing restraint.[15] Hence, the Senate Report underscores the principle that evidence of a suspect transaction or activity that is known to a director must be questioned and examined diligently and thoroughly, regardless of the views of other experts.

The implications for independent directors are enormous. The days when an independent director held several of such appointments concurrently are likely to be over. Independent directors may have to be selective in choosing appointments so as not to spread themselves too thinly. They must also be prepared to commit resources and time and change the mindset that their appointment is a "part-time" one. They may also have to assess the risks of companies to determine if they are willing to undertake the fiduciary responsibility of monitoring such a company.

Conclusion

The Enron case has painful lessons for the business community. A seemingly successful company was apparently derailed through the use of highly risky transactions and aggressive accounting that temporarily boosted profits and reduced debt. The question arises as to why the corporate guardians of Enron did not prevent these transactions from occurring. Following Enron and other accounting scandals, a re-examination needs to be carried out of the role and responsibilities of independent directors. This paper suggests that significantly greater challenges are posed to independent directors in a post-Enron world to understand more of the risks, accounting practices, and managerial opportunism existing in the companies under their purview and to take a more proactive role in governance, which inevitably requires a substantial commitment of their time and resources.

Abstract

This paper introduces the agent-based modeling methodology and points out the strengths of this method over traditional analytical methods of neoclassical economics. In addition, the various design issues that will be encountered in the design of an agent-based financial market are discussed.

41.1 Introduction

The sort of phenomena that are interesting in finance and yet difficult to investigate analytically involve the complex interactions among many self-interested heterogeneous boundedly rational agents acting within the constraints imposed by either formal or informal institutions or authorities. To outrival their opponents, each and every agent must continually evolve to adapt to changes that may arise either from exogenous perturbations to the environment or endogenous transitions caused by agents changing their strategies or modifying their behaviors as they learn more about the behaviors of the other agents and the environment they reside in. A good example of such complex adaptive systems is the stock market.

A natural way to study a complex adaptive system like the stock market is to use an agent-based model which entails simulating the stock market on a computer from the bottom up with a large number of interacting heterogeneous boundedly rational artificial agents that are created to mimic the traders in the stock market. Once the environment of the stock market and the behaviors of the agents are specified and the initial state of the model is set, the dynamics of the model from the initial state forward will be driven entirely by agent–agent interactions, and not by some exogenously determined systems of equations. Hence, if any macroscopic regularity emerges from the model, it must be a product of the endogenous repeated local interactions of the autonomous agents and the overall institutional constraints. This is the spirit of the agent-based modeling approach.

What makes the agent-based modeling methodology particularly appealing? To begin with, analytical tractability is not an issue since this approach relies on computer simulations to understand the complex model. Quite the reverse, it is inconceivable how one could obtain closed form solutions of a model as complex as the stock market without first diluting drastically the authenticity of the model. Although analytically tractable heterogeneous agent rational expectations models have been around, the complexity and realism that are captured in agent-based models are beyond the reach of those analytical models.

For instance, consider the problem that a decision maker faces when the outcome is contingent on the decisions to be made by all the participating heterogeneous decision makers, each with their own unique preferences and quirks and private information that are not directly observable by the other decision makers. This decision problem is

N.S.P. Tay (✉)

University of San Francisco, San Francisco, CA, USA

e-mail: tay@usfca.edu

inherently ill defined and cannot be solved through mathematical deduction or analytical modeling. In real life, when confronted with such an ill-defined situation, decision makers often rely on the rules of thumb that they have distilled from years and years of experience to guide them in their decision-making. This decision making process is formally known as inductive reasoning and it can be captured naturally with the agent-based approach by running computer simulations of a large number of interacting artificial agents who make decisions using rules of thumb that they distill from their repeated interactions with each other.

The ability to build more realistic models with the agent-based method often allows agent-based models to reveal a much richer set of behaviors that are embedded in a system which may otherwise be overlooked by traditional equation-based models. For instance, Parunak et al. (1998) in comparing the differences between equation-based modeling and agent-based modeling of a supply network have found that equation-based model fails to produce many of the rich effects, such as memory effect of backlogged orders, transition effects, or the amplification of order variation, which are observed in an agent-based model of the same supply network. In addition, various agent-based models (Farmer and Joshi, 2000; Johnson et al., 2001; LeBaron et al., 1999; Tay and Linn, 2001) have been successful in accounting for real financial markets phenomena such as market crashes, mean reversion, relatively high level of trading, technical trading, excess volatility, and volatility clustering. These are phenomena that analytical representative agent models of financial markets have tolled to explain without much success.

Another serious shortcoming of analytical representative agent models of financial markets is that by design these models do not specify the dynamic process that will need to happen in order to arrive at the equilibrium or equilibria that are characterized in these models. Consequently, for models that produce multiple equilibria, it is unclear which equilibrium among the multiple equilibria agents would converge on. In contrast, the events that unfold in a computer simulation of an agent-based model are completely transparent, and can be recorded hence providing the modeler a means to go back in the time line of evolution to understand how certain equilibrium or other global regularities came into existence.

The agent-based methodology therefore offers important advantages over the traditional analytical tools of neoclassical economics as it allows a researcher to obtain more germane results. Needless to say, the use of computer simulations as a tool for studying complex models has only became feasible in recent years because of the availability of fast and cheap computing power. Although the agent-based modeling methodology is still in its infancy, there is already a considerable literature on agent-based models. Leigh

Tesfatsion at the Iowa State University maintains a website at http://www.econ.iastate.edu/tesfatsi/ace.htm to facilitate access to the extensive resources related to the agent-based modeling methodology, and to keep researchers in this field abreast of the latest developments.

In the introductory remarks on her website, Tesfatsion observes that agent-based research may generally be organized according to one of the following four research objectives: (1) empirical understanding, (2) normative understanding, (3) qualitative insight and theory generation, and (4) methodological advancement. The first objective focuses on seeking answers that are established on the repeated interactions of agents to explain the emergence of global regularities in agent-based models. Some examples of global regularities in financial markets are mean reversion and volatility clustering. Researchers in this group are interested in understanding if certain types of observed global regularities can be attributed to certain types of agent-based worlds. The second objective concerns using agent-based models as laboratories to aid in the discovery and design of good economic policies or good institutional structures. Researchers with this objective in mind are interested in using agent-based models to evaluate whether certain economic policies or institutional designs and processes will promote socially desirable outcomes over time among agents that are driven solely by their self interests. Tesfatsion phrased the third objective as "How can the full potentiality of economic systems be better understood through a better understanding of their complete phase portraits (equilibria plus basins of attraction)?" Unlike analytical models, the causal mechanisms in agent-based models are not direct and are very difficult to discern because of the complex nature of the interactions among the agents and between the agents and the environment. The goal here is to use the phase portraits as a means to enrich our understanding of the causal mechanism in these systems. The fourth objective addresses issues related to improving the methods and tools used by agent-based researchers.

For someone who is just starting out in this line of research, it is worthwhile to begin by reading "A Guide for Newcomers to Agent-based Modeling in the Social Sciences" by Axelrod and Tesfatsion which is available on the homepage of Tesfatsion's website. In addition, it is beneficial to read the survey articles written by Hommes (2006), Duffy (2006), LeBaron et al. (1999), LeBaron (2000, 2006), and Tesfatsion (2002) and a book by Batten (2000) that provides an overview of agent-based models and offers some historical perspectives of this methodology.

The next section discusses the design issues that will be encountered in the design of an agent-based model. This discussion benefited greatly from the insights that LeBaron has provided in his excellent overviews of the various design issues (LeBaron, 2000, 2001c, 2004a).

41.2 Design Considerations

A typical agent-based model is made up of a set of autonomous agents that encapsulate the behaviors of the various individuals in a system we are interested in studying and the investigation involves simulating on a computer the interactions of these agents over time. Accordingly, there are two important design considerations in the development of an agent-based model – the design of the agents and the design of the environment.

How naive or sophisticated the agents should be modeled really depends on the objective of the research. For instance, if the research objective is to understand how certain market structures affect the allocative efficiency of a market independent of the intelligence of the agents as in Gode and Sunder (1993), then one can simply model the agents as naive "zero intelligence" agents. Zero intelligence agents are agents that are not capable of formulating strategies or learning from their experience; hence their behaviors will be completely random. Gode and Sunder populated their double auction market with zero intelligence agents that are designed to submit their bids and asks at random over a predefined range and remarkably they discover that zero intelligence agents when subjected to a budget constraint are able to allocate the assets in the market at over 97% efficiency. The lesson to be learned here is that not all macroscopic regularities that emerge from agent-based models are necessarily consequences of the actions taken by the agents as they evolve and learn from their interactions. In this case, the high level of allocative efficiency that is attained in a double auction market is due to the unique structure of the market itself.

However, in many agent-based models, the objective is to investigate the outcome of the interactions among many heterogeneous agents that are designed to mimic their counterparts in the real world. In these models, the key design issues related to the design of the agents are the agents' preferences and their decision-making behaviors. Agents could have either myopic or intertemporal preferences. The latter is more realistic but will make the model much more complex. As we have alluded to earlier, the decision problem that the agents face is usually ill defined, and thus cannot be solved by deductive reasoning. A reasonable solution is to assume that the agents rely on inductive reasoning to arrive at a decision (see Arthur, 1994, 1999; Rescher, 1980). Inductive reasoning or induction is a means for finding the best available answers to questions that transcend the information at hand. In real life, we often have to draw conclusions based upon incomplete information. In these instances, logical deduction fails because the information we have in hand leaves gaps in our reasoning. In order to complete our reasoning, we fill those gaps in the least

risky, minimally problematic way, as determined by plausible best-fit considerations. Consequently, the conclusions we draw using induction are suggested by the data at hand rather than logically deduced from them.

Inductive reasoning follows a two-step process: possibility elaboration and possibility reduction. The first step involves creating a spectrum of plausible alternatives based on our experience and the information available. In the second step, these alternatives are tested to see how well they answer the question at hand or how well they connect the existing incomplete premises to explain the data observed. The alternative offering the "best fit" is then accepted as a viable explanation. Subsequently, when new information becomes available or when the underlying premises change, the fit of the current alternative may degrade. When this happens a better alternative will take over.

How can inductive reasoning be implemented in an agent-based financial market model? Arthur (1994, 1999) envisions inductive reasoning in a financial market, taking place as follows. Initially, each agent in the market creates a multitude of decision-making rules (this corresponds to the possibility elaboration step discussed above). Next, the decision-making rules are simultaneously tested for their effectiveness based on some criteria. Finally, effective decision-making rules are retained and acted upon in buying and selling decisions. Conversely, unreliable rules are dropped (this corresponds to the possibility reduction step). The rules that are dropped are then replaced with new ones in the first step and the process is carried out repeatedly to model how individuals learn inductively in a constantly evolving financial market.

Some examples of criteria that have been used for appraising the effectiveness of the decision rules includes utility maximization, wealth maximization, and forecast errors minimization. Once a decision has been made on a criterion for evaluating the decision-making rules, the next task is to decide the length of historical data to be used in computing the criterion. Although many agent-based models tend to allow the agents to adopt identical history length, this is not necessary. It is in fact more realistic to permit agents in the same model to adopt different history length as in LeBaron (2001a, b).

To take the modeling to the next step, decision will have to be made concerning what the decision making rules look like and how they are to be generated in the models? One possibility is to model the decision-making rules after actual trading strategies used in real financial markets. The benefit of this approach is that the results are likely to be tractable and precise and it will also shed light on the interaction among these actual trading strategies. However, this approach does not allow the agents any flexibility in modifying the strategies or developing new strategies. This could impose ad hoc restrictions on the model's dynamics.

Some common tools that have been employed to allow the agents more degrees of freedom in structuring and manipulating the decision making rules as they learn are artificial neural networks (LeBaron, 2001a), genetic programming (Chen and Yeh, 2001), and classifiers that are evolved with genetic algorithms (LeBaron et al., 1999). Even with these artificial intelligence tools, the modeler will need to predefine a set of information variables and functional forms to be used in the strategies or decision-making rules. Although these tools can successfully mimic the inductive reasoning process described earlier, it is not known if any of these tools indeed faithfully represent the inductive reasoning used by actual human traders. It is also unclear at this juncture whether this issue matters. Another related decision that has to be made by the modeler concerns whether the agents should be allowed to learn only from their own experiences or from the collective experience of all the agents in the model. The latter is known as "social learning."

We will turn our attention next to the design of the financial market environment. Most agent-based models simplify the environment to a market with one risky asset and one risk-free asset. Clearly, this is an oversimplification of actual financial markets, but there are good reasons for doing so. Given that the agent-based methodology is new and researchers barely comprehend the implications of this methodology, it is prudent for them to begin by exploring what the new method can reveal about the dynamics in a fairly simple market environment. Moreover, doing so also facilitates comparisons with results from well-known neoclassical models of a market with one risky asset and one risk-free asset.

Another key design issue concerns the design of the trading mechanism that has a direct influence on how prices are determined in the market and how the market is cleared. LeBaron (2004a) observes that most of the agent-based models employ one of the following four designs for trading mechanism. The simplest trading mechanism is one that allows mutually beneficial trades to be consummated between agents that meet at random. Though this trading mechanism is quite simple, it bears some resemblance to the trades conducted on the floor of the Chicago futures and options exchanges and over the telephone in the foreign exchange markets. But for markets where the market makers play an important role in filling the buy and sell orders, this mechanism would not be an adequate representation. A second trading mechanism, which is more sophisticated than the previous one is an analytical market-clearing device akin to one espoused in Grossman (1976). This device provides a closed form solution for the market-clearing price hence enabling the agent-based markets to be cleared analytically each period. A critical advantage of this design is that it avoids having to deal with the difficult issue of explicitly modeling the decision-making behaviors of the

risk-adverse market maker. Unfortunately, this advantage is also a serious shortcoming in that this is not a realistic picture of what is happening in real markets that trade continuously and are rarely in equilibrium. The third trading mechanism attempts to address this issue. It assumes that agents submit trade orders to buy (D_t) and sell (S_t) at a price, p_t, which is announced beforehand by a market maker. The market maker then appraises the aggregate of the orders submitted by the agents, and adjusts next period price by a fixed fraction of the excess demand or supply according to $p_{t+1} = p_t + \alpha(D(p_t) - S(p_t))$. Granted that this adaptive price process may be a more reasonable model of how prices adjust in real markets, the problem with this mechanism is that it does not address how the market maker manages the imbalance between demand and supply in the market. Moreover, there is no guidance on how the parameter value for α should be determined and certain α values may in fact cause the market to deviate far from the market clearing price for a substantial period. The most sophisticated and also the most realistic trading mechanism is one that either models the market maker explicitly or implements an order book system that can accept and cross out the buy and sell orders from agents according to some defined procedure (Audet et al., 2001). The only downside of this approach is that the design of the agent-based model is much more complicated as many details at the institutional as well as the agent level will need to be clearly specified. But, this is inevitable if the objective is to simulate realistic market microstructure behavior.

To sum up, there are many design questions that need to be addressed in the development of an agent-based model and there is yet no clear guidance on how best to address these questions. Inevitably, design decisions will have to be made however arbitrary these decisions may be but it is important to keep in mind that the choices made by the designer may ultimately have important consequences on the results.

Abstract

One major factor that led to the 1997 Southeast Asian financial crisis was the reliance of the afflicted nations on heavy borrowing from western banks. The crisis has shown the massive need for establishing a regional bond market. Given the huge foreign reserves held by Asian central banks, at present, it is crucial to create a vehicle in order to preserve Asian capital within the region.

Recent progress has been made in the direction of creating regional bond markets in the areas of Asian Bond Fund (ABF) that deals in foreign currency and Asian Basket Currency (ABC) bonds that deals in local currency.

The past few years have seen major improvements in the issuance of Asian government bonds. Yet, the area of corporate bonds in the region still remains clearly underdeveloped due to the lack of credit ratings at investment-grade. Addressing the issue of ratings is one of the real challenges that must be overcome before the Asian region could have a viable bond market.

42.1   Introduction

Before the Southeast Asia financial crisis, the standard works on the role of capital markets in economic growth (Goldsmith, 1965, 1985; Hakansson, 1992; McKinnon, 1971, 1991) had focused mainly on the *equity* markets. Thus, the establishment of bond market in emerging nations has not received the attention it deserves in the finance literature.[1] For decades, the emerging economies in Asia had grown rapidly without the presence of an active bond market (Dalla et al., 1995;

Emery, 1997; Levine, 1997; Sheng, 1994; Yam, 1997). In these economies, bond markets are very small relative to equity markets and the banking system.[2] One of the reasons that enticed Asian firms to borrow heavily from western banks before 1997 was the lack of an Asian bond market.[3] A major consequence of the crisis was to breathe life into the concept of setting up an Asian bond market in order to enhance financial stability (Alba et al., 1999; Rhee, 2003; Tourk, 2004).

A viable bond market gives the society a true measure of the opportunity cost of funds. In the absence of such market there is a loss of an important signal to channel savings into proper investments.[4] Another drawback is the distortion of the incentives for risk taking which raises the specter of a banking crisis.[5]

K. Tourk (✉)
Illinois Institute of Technology, Evanston, IL, USA
e-mail: tourk@stuart.iit.edu

Overdependence on bank borrowing means that banks can extract rents from the borrowers as the cost of borrowing is higher than the case where firms have the option of accessing funds from a bond market.[6] Long-term investment is also biased under bank-centered loans since banking institutions tend to offer loans for periods that are significantly shorter than the life span of long-term bonds.

The concept of an Asian bond market is not a new one. The original idea was proposed by the Asian Development Bank, which in the early 1990s issued dollar denominated "Dragon Bonds."[7] The target of these bonds was the Asian investor. Unfortunately, the bonds did not succeed in attracting enough demand because of their low liquidity.

After 1997, the idea of an Asian bond as a vehicle to preserve long-term Asian capital within the region was a direct response to the financial crisis. The new initiative was taken by Japan's Ministry of Finance (MOF). It was supported by the United States. Thanks to the enthusiastic promotion by the Thai Prime Minister Thansin Shinawatra, the Asian bond market has become a reality. He floated the idea in October 2002, at the East Asian Economic Summit organized by the World Economic Forum. Stemming from this, an Asian Bond Fund was established in June 2003 by the head of central banks in the region.

The *raison d'etre* of the fund is for Asian governments and other entities to issue bonds in order to reinvest part of the region's savings in Asia itself (Oh et al., 2003; Sonakul, 2000). "Since bond rating and settlement is to be handled within the region, the use of dollar bonds will become unnecessary. Eventually it should be possible to issue bonds denominated in regional currency or a basket of regional currencies."[8]

Developing local bond market (Mungthin, 2000) is important in reducing the Asian countries exposure to maturity and exchange rate risks and "sudden stops" in the availability of international capital.[9] The benefits include an increase in the efficiency of allocating surplus funds and the retention of Asian capital. In 2004, central banks of Asia held roughly $1.1 trillion of US Treasuries. In just 2 years beginning at the start of 2002, the dollar dropped around 26% against a basket of six major currencies.[10]

For Asian corporations, they benefit from the diversification of funding sources (i.e. less reliance on borrowing from domestic banks) and improving transparency, leading to better corporate governance. Another advantage is that it would give Asian governments more policy instruments to stabilize their financial markets.[11]

The Asian Bond Market has taken two forms: first an Asian bond market led by East Asia-Pacific (EMEAP) Central Banks and the second is represented by the Asian Bond Market Initiative (ABMI), proposed in 2002 by Japan's MOF, and under the supervision of the ASEAN + 3 finance ministers.

42.2 The Asian Bond Market Launched by EMEAP Central Banks

At the beginning of 2005, the foreign exchange reserves in the Asian regions were around $2 trillion dollars, which equals more than 50% of the world's reserves.[12] These Asian resources could be channeled into banking, as well as other types of finance,[13] to enable Asian nations to create wealth in each other's economy. Thus, the necessity to establish an infrastructure for bond markets, both primary and secondary. Recent progress has been made in the direction of creating regional bond markets in the areas of Asian Bond Fund (ABF) that deals in *foreign* currency and Asian Basket Currency (ABC) bonds that deals in *local* currency.[14]

The first Asian bond fund (ABF-1) was launched in June 2003 by the central banks of the 11 countries who are members of EMEAP.[15] It consists of $1 billion worth of foreign reserves, which is being invested in a basket of *dollar-denominated* bonds issued in eight Asian economies[16] by sovereign and quasi-sovereign entities in the EMEAP countries, except in Japan, Australia, and New Zealand. The Bank of International Settlements (BIS) will be managing the fund. It has been indicated that the 11-member group plan to consider extending ABF investments to bonds denominated in *Asian* currencies. In December 2004, a second fund was launched with $2 billion in governments' capital to invest in corporate debt issued in local currencies.[17]

42.3 The Asian Bond Market Initiative (ABMI)

The Asian Bond Market Initiative (ABMI) is focused on the creation of a proper environment where access by a wider variety of issuers to the regional bond markets is facilitated (Taniguchi, 2003). Since summer of 2003, working groups representing the ASEAN + 3 finance ministers have defined specific subjects to be reported on to the ASEAN + 3 finance ministers meeting in 2004.[18]

One important step in the creation of proper environment is for the government to establish a benchmark yield curve to serve as the risk-free rate for the pricing of other securities.[19] A program of regular issues at appropriate maturities (e.g., 3 month, 6 month, 1 year, 3 years, 5 years, and eventually 10 years) should be set up.[20] The interest rate on government bond should be market-determined. It must be kept in mind that minimizing the cost of government borrowing may be in conflict with the development of this market-determined rate. Thus, the government should refrain from any manipulation of the bond market (i.e. requiring some institutions to hold government debt, devising preferential tax treatment for public sector debt) with the purpose of reducing the cost

of its borrowing. Doing that would negatively affect the efficiency of the bond market and lead to distortions in the allocation of capital.[20]

42.4   The ABC Bond Corporation

The creation of the ABC bond corporation, dealing in local currency, is the result of a Japanese MOF initiative. One major benefit of the ABC government bonds is that they represent a benchmark for the region. Ito (2003a, b) proposed the establishment of this corporation in order to serve as a depository for financial assets supplied by participating governments in the form of local currency denominated government bonds.

For the ABC government bonds to be priced correctly, it is important that the public sector should be vigorously involved in establishing a deep domestic bond market. Governments must cooperate to issue standardized bonds that can be put into depository to form a standardized basket (i.e. standardized maturity; standardized interest rate calculation, pre-announced coordinated issuance schedule, interest payment methods, depository location).[21] To reduce the weight of the dollar in Asian foreign reserves, ABC bonds that are issued offshore will be treated as foreign reserves.

In the first phase, the ABC Bond Corporation would issue bonds that match the value of the assets. In the second phase, the Corporation may issue bonds that match the value of corporate bonds denominated in various Asian currencies. As such, the ABC Bond Corporation operates along the same lines as a Special Purpose Vehicle (SPV) with asset-backed securities. It is here that the private sector can establish a corporate bond market and asset-backed securities denominated in the basket currency. Corporate bonds are brought into the depository, just like government bonds, and ABC corporate bonds can be issued. The benchmark yield is provided by the ABC sovereign bonds. Because the credit risk is higher, the yield would also be higher. Furthermore, as these bonds can now be sold in the region at large, instead of one country alone, this would reduce the issuing costs. Another advantage is the direct relationship between investors and borrowers.

One major attraction of issuing ABC bonds is that they will diversify currency risk. Firms exporting in the Asian region will issue liabilities that match their revenue streams denominated in the local currencies. By being less dependent on bank loans they will be less affected by banking crisis.[22]

The ABC Bond Corporation operates as an issuer of bonds to be bought by Asian institutional investors. Expected buyers of the ABC bonds include Asian central banks and pension funds. They also includes institutional investors, both Asian and foreign. This is different from the ABF, which serves as an investment vehicle for Asian central banks, acting as a buyer of dollar denominated bonds issued by Asian borrowers.

It should be kept in mind that since pension funds and central banks tend to have passive investment strategies, both the ABF and ABC invested bonds might not be powerful enough instruments in the promotion of market liquidity on the secondary market.[23]

42.5   Credit Enhancement

As explained above, the bonds issued by the ABC Bond Corporation match the value of the underlying assets of this entity, which are denominated in government bonds of various Asian currencies. Even though pledged bonds are backed by full faith and credit of participating Asian governments, the question of credit enhancement comes into play because international rating agencies view various governments differently with respect to credit risk. The enhancement could be either *internal* or *external*.

The most used form of internal enhancement is through the restructuring of the distribution of pooled cash flows to create a new instrument called a Collateralized Bond Obligation (CBO). Under this system, two tranches of ABC bonds could be issued: senior bonds with higher credit rating and lower yields and subordinate bonds with lower credit rating but higher yields.[24]

External enhancement includes third party guarantees provided by official financial institutions (e.g. Development Bank of Singapore, ADB, JBIC), letters of credit by leading international commercial banks and bond insurance provided by monoline bond companies.[25]

In order to transform Asian corporate bonds from speculative-grade assets to investment-grade assets, Asian governments, Asian banks, and Asian credit insurers could offer full or partial guarantees on the issuer. This will facilitate the issuance of credit insurance by top-rated insurers to bond issuers with poor credit ratings. Asian governments could also play an important role in strengthening a system of Asian-based credit insurers.[26]

42.6   Securitized Asian Corporate Bonds

The past few years have seen major improvements in the issuance of Asian government bonds. Yet, the area of corporate bonds in the region still remains clearly underdeveloped (Claessens et al., 1998) due to the lack of credit ratings at investment-grade.

One way to raise the quality of Asian corporate bonds to investment-grade assets is to pool the bonds together making them securitized corporate bonds. A large asset pool of this

kind can be listed and traded on the exchange or in the OTC market. This has the advantage of satisfying the market demand for high-yield assets with credit protection. These assets are considered safe because top-rated credit insurers insure the cash flows from the bonds.

So far, Asian securitization has developed very slowly in the region.[27] At present, the investor base for Asian corporate bonds is extremely narrow. While credit enhancement would increase the participation of both Asian institutional and international investors, there is also a need to attract *individual* investors to be active participants in Asian debts. In this regard, the government policies could be important in developing bonds of smaller par value that the general public is enticed to invest in.

Another policy is government support of mutual funds that invest primarily in Asian *corporate* bonds. An encouraging development is the establishment of the Asian bond fund whose objective is to invest in Asian debt securities. It was established in May 2003, by nine Asian governments, where each contributed up to 1% of its foreign reserve to the fund. These governments consist of Thailand, China, Japan, Hong Kong SAR, South Korea, Singapore, Indonesia, Malaysia, and the Philippines. It has been suggested that in order to encourage the participation of individual investors,[28] the government bond fund can be further securitized to become either a closed or open-ended fund.[29] Assets in the fund must be insured in order to minimize the credit risk of individual investors. Due to its large market capitalization and prospective large number of investors, both institutional and individual, the liquid government bond fund can flourish into an actively traded asset capable of nurturing a number of financial derivatives. Such derivatives would enable international investors and credit insurers to hedge the credit and market risk in Asia. In short, the Asian governments can play a crucial role in asset securitization that would transform sovereign and corporate debts into attractive investment vehicles for the general public.[30]

42.7 Efficient Financial Intermediaries

An integral part of creating bond markets is the development of an efficient pension and insurance systems. The main advantage of the financial intermediaries, such as pension funds and insurance companies, is the ability to invest in financial instruments other than government bonds. Credit-worthy Asian corporations would be able to borrow long-term.

In addition to expanding the finance choices for the private sector, many governments in Asia might find it preferable to develop a yield curve in order to meet their budget deficit obligations. Except for Japan, which has a well-developed bond market, there are still many barriers that must be overcome before it becomes a reality in other parts of Asia.[31] The barriers include weak financial institutions, restrictive investment eligibility requirements, and antiquated transfer, trust, title, and tax policies.[32]

Another major difficulty is the reluctance of international rating agencies[33] to analyze the credit worthiness of Asian corporations. Many of these corporations are family owned and there is a lack of information regarding their financial standing. Thus, poor credit ratings, as assessed by the dominant international rating agencies, are one of the main reasons preventing Asian corporations of issuing unsecured bonds.[34]

To conclude, the challenge facing Asia is to set up a deep and broad bond market.[35] One difficulty is that each country's emerging economy is relatively small. The region has many national currencies. This is in contrast to the Europe where the combined bond market denominated in euro is now poised to rival the American dollar-denominated market.[36] Another related challenge is the present dominant role played by the American currency as a large number of Asian currencies remain tied to the American dollar. On the positive side, the region is witnessing the rise of a plethora of Free Trade Agreements.[37] Asian central banks are in control of huge foreign exchange reserves. This bodes well for the eventual creation of an East Asian monetary union and the introduction of a single currency, most probably in the distant future. In fact, the concept of ABC bonds might be looked upon as antecedent to an Asian common currency.

Notes

1. Arnoud Boot and Angan Thakor, "Financial System Architecture", *Review of Financial Studies*, Vol. 10, no. 3, pp. 693–733 (Boot and Thakor, 1997).

3. At the end of 2001, the total outstanding amount issued by Asian emerging borrowers in local and international capital markets showed rapid increase, reaching $1.1 trillion. According to the IMF, in comparison with other regions, "emerging Asia has issued less international bonds (13% of the Asian total outstanding), more government bonds in local markets, but not so dominating (50%), and a large private sector share: 20% for financial institutions and 17% for corporate. The composition of the Asian bond markets is thus similar to that of mature bond markets: domestic governments bonds account for 49%, financial institutions 22%, corporate 11%, and international bonds 18%. By contrast, Latin America has issued

more international bonds (32% – mainly by sovereign borrowers) and government bonds in local markets (55%), leaving a small share for the private sector (13%). Similarly, EMEA (Eastern Europe, Middle East, Africa) has also issued more international bonds (23%) and government bonds in local markets (73%), with a negligible share of 4% for the private sector." Huan Q Tran and Jorge Roldos "Asian Bond Markets, The Role of Securitization and Credit Guarantees" *The 2nd ASEAN Central Bank Governor's Meeting*, Bangkok – 8,9/6/2003, p.2 (Tran and Roldos, 2003).

4. For example, lacking such signal, firms would over-invest if their internal rate of return is too low, as happened in many emerging economies in Asia during the 1990s.

5. This is particularly true when banks are undercapitalized. In such cases, making a write down in a loan renegotiation might result in violating capital adequacy standards. To avoid declaration of default, some banks might find it expedient to continue funding borrowers with negative present value projects. This exposes the banking system to liquidity shock. Without a bond market, banks do not have the option of selling bonds in a secondary market. Thus, they are likely to accept large losses on the sale of bad loans.

18. Hisatsugu Nagao, op. cit. p. 39.

19. In practice, government issues provide the benchmark for estimating term structure of interest rate. These issues are approximately default risk-free in domestic currency terms.

20. Richard J. Herring and Nathporn Chatusripitak, op. cit. p. 25.

21. Takatoshi Ito, Asian Basket Currency (ABC) Bonds, February 2003.

22. Takatoshi Ito, "Promoting Asian Basket Currency (ABC) Bonds," RCAST, University of Tokyo, March 1, 2003.

23. For the trade-off between liquidity and foreign exchange risk in the case of basket-denominated bonds, see Oiji Ogawa and Junko Shimizu, "Bond issuers' trade-off for common currency basket denominated bonds in East Asia," *Journal of Asian Economics*, Vol. 15, 2004, pp. 719–738 (Ogawa and Shimizu, 2004).

24. This type of senior/subordinated bond issue was extremely popular in the post crisis period in Korea. See Gyutaeg Oh, Daekeun Park, Jaeha Park and Doo Yong Yang, 'How to Mobilize the Asian Savings within the Region: Securitization and Credit Enhancement for the Development of East Asia's Bond Market', *Korea Institute for International Economic Policy Working Paper* 03–02, 2003.

25. Many monoline bond insurance companies operate in the United States and Europe providing municipal bond insurance and pool insurance.

26. The first regional bond insurance company was established by the Asian Development Bank (ADB) in

Singapore in 1995. This company was named as the Asian Securitization and Infrastructure Assurance Ltd (ASIA Ltd). Its owners consist of a diverse group consisting of financial institutions, ADB member countries, insurance companies in addition to others. Primarily, ASIA Ltd offers credit insurance to infrastructure projects of developing nations. Richard Yan Ki Ho and Chak Sham Michael Wong, "Road Map for Building the Institutional Foundation for Regional Bond Market in East Asia", *Second Annual Conference of the PECC Finance Forum*, op. cit. p. 21 (Ho and Wong, 2003).

27. Korea has been an exception, being relatively active in this field. Korea set up a system of Primary Collateralized Bond Obligation in the year 2000. This program was introduced via the Korea Credit Guarantee Fund. In Hong Kong, the Mortgage Corporation, a subsidiary of the Hong Kong Monetary Authority, deals with mortgage securitization. Korea has enacted the Securitization Act in order to provide a workable legal system to facilitate the securitization of banks' nonperforming loans in addition to restructuring the balance sheet of financially troubled corporations.

28. For the benefit of institutional investors, the Hong Kong Monetary Authority issues Exchange Fund Bills and Notes. They are akin to U.S. treasury securities. The Authority started to issue smaller Exchange Fund Notes of around $7000 per contract in 2000. These notes are popular among the general public.

29. Richard Yan Ki Ho and Chak Sham Michael Wong, "Road Map for Building the Institutional Foundation for Regional Bond Market in East Asia", *Second Annual Conference of the PECC Finance Forum*, op. cit. p. 26 (Ho and Wong, 2003).

30. During the South East Asian Crisis, the Hong Kong government took a pro-active stand against the attacks of global hedge funds speculators. To protect the stock market, the "equities purchased at that time were securitized to become a fund known as Tracker Fund. All the units of the Fund were later sold to both institutional and individual investors." Richard Yan Ki Ho and Chak Sham Michael Wong, "Road Map for Building the Institutional Foundation for Regional Bond Market in East Asia", *Second Annual Conference of the PECC Finance Forum*, op. cit., p. 26 (Ho and Wong, 2003).

31. In 2003, Japan had a $5 trillion market, which is roughly equal to its gross domestic product. China, on the other hand, has less than $450 billion in issues outstanding representing 32% of its GDP.[1] Marshall Mays and Michael Preiss, "Asia must put its savings to work", *Financial Times*, November 7, 2003, p. 15 (Mays and Preiss, 2003).

32. Marshall Mays and Michael Preiss, op. cit., p. 15.

33. In the long term there is a need to establish Asian rating agencies. Practically however, it will take a few decades before the dominance of international rating agencies could be seriously challenged.

34. It has been estimated that for Asian corporations with less favorable credit ratings, the funding costs of issuing unsecured Asian corporation bonds could be higher than 18%. This is why many corporations in Asia prefer to acquire collateral pledged bank loans at an interest rate varying between 5% and 10%. Richard Yan Ki Ho and Chak Sham, Michael Wong, "Road Map for Building the Institutional Foundation for Regional Bond Market in East Asia", *Second Annual Conference of the PECC Finance Forum*, op. cit. p. 16.

35. A deep market means the bond quantity can be sold without moving prices against the seller. Breadth signifies the diversity of participants and the heterogeneity of their responses to new information.

36. Richard J. Herring and Nathporn Chatusripitak, op. cit. p. 27.

37. A free trade area is formed when a group of nations agree to eliminate tariffs between themselves, but maintain their external tariffs on imports from the rest of the world.

Cross-Border Mergers and Acquisitions

Geraldo M. Vasconcellos and Richard J. Kish

Abstract

Cross-border mergers and acquisitions have shown tremendous growth over time primarily due to a desire to circumvent tariffs and nontariff barriers arising from arms-length international trade and taxes; to obtain new options for financing; to access technology; and to distribute research and development costs over a broader base. Several factors put in place to moderate this growth include protecting key industries, limiting controlling interest levels, and restricting remittances of profits and dividends. This paper focuses on cross-border mergers and acquisitions, and their financial and economic (both macro and micro) underpinnings, which affect their direction and magnitude. In general terms, empirical analysis supports the fact that both a host country's and the foreign country's stock and bond prices are major causal factors that influence cross-border mergers and acquisitions.

Keywords

Acquisition • Barriers • Cross-border • Diversification • International • Mergers • Multinational • Synergy • Takeovers • Tariffs • Undervaluation

One of the remarkable developments that accompanied the vigorous growth in international trade in the post-World War II era has been an unabated increase in international direct investment. This phenomenon, including its theoretical underpinnings, benefits and costs, has been the subject of voluminous research. In addition, many studies have examined the attendant questions of the host country attitudes toward international direct investment. Extant research suggests that some of the main benefits of international direct investment can be found in the avoidance of tariffs and nontariff barriers to arms-length international trade, in tax incentives usually associated with efforts to attract foreign investment to a particular country or region within a country, in the ability to tap different markets for short-term and long-term capital, and in the possibility of obtaining quicker and cheaper access to superior technology, as well as the ability to spread out the output of a multinational corporation's own research and development efforts over a broader market base. On the other hand, risks and constraints affecting international direct investment include closed sectors or industries, limitations on the acquisition of a controlling interest in a foreign company, limitations on remittances of profits and dividends, limitations on cross-border mergers and acquisitions and, in some extreme cases, the possibility of expropriation (Madura et al., 1991).

The countries affiliated with the Organization for Economic Cooperation and Development (which includes all the major advanced market economies) lead this impressive growth in international direct investment. The outward direct investment flows are in general larger than the inward flows. The reason is that OECD countries invest in non-OECD countries, generally less developed ones. The inward flows of foreign direct investment (FDI) in OECD countries come almost exclusively from other OECD countries, that is to say, other major industrial countries. For example, during the 1980s, the United States was the major recipient of flows of international direct investment, followed by Europe and

G.M. Vasconcellos (✉) • R.J. Kish
Lehigh University, Bethlehem, PA, USA
e-mail: gmv0@lehigh.edu

Canada in more modest terms. Japan was the main source of flows of international direct investment. This helps to explain why the United States gave up its position as the world's largest creditor nation to become the world's largest debtor in less than a decade. In the same period of time, Japan became one of the largest creditors. The direct investment flows, however, explain only one part of these transformations. The rest of the explanation is found in portfolio investments and their reallocations.

The acquisition of a foreign firm is one of the fastest methods of entering into a foreign market. In the late 1980s and the 1990s, this method seemed especially attractive to businesses wanting to become involved in the evolving European market. As a result, there was a surge of foreign takeovers in the European Union during this period. This demonstrated that businesses had confidence in the E.U., forming a single internal market in the long run. In fact, many of these acquisitions took place before national barriers came down. The rationale for this may be attributed in part to a growing concern that a unified Europe could translate into a more protectionist "Fortress Europe." Many foreign companies believed that the only way to participate in a unified Europe was to quickly become an insider. Acquisitions subsided after the initial surge that took place in the late 1980s, due to the creation of natural barriers to entry for outsiders. Many mergers and acquisitions were taking place within the E.U., creating larger, more efficient European businesses and effectively producing fewer opportunities for foreign companies. By the early 1990s, however, acquisitions of European firms were on the rise again due to two primary factors: (1) a need to complete the restructuring that had begun in the 1980s and that could not be done by European firms alone; and (2) regulatory changes that enabled hostile takeovers to occur more easily. But this rise in U.S. acquisitions of E.U. companies was followed by a rise in E.U. acquisitions of U.S. firms, a cycle that seem to exist within many areas of the world economy.

International direct investment, therefore, takes place in basically two forms: *de novo* entry or mergers and acquisitions. This review focuses on cross-border mergers and acquisitions, their financial and economic underpinnings, and the factors, which affect their direction and magnitude. FDI is an integral part of the developed capital markets. The significant rise in the number of cross-border mergers and acquisitions across time warrants a better understanding of the factors affecting these activities. For example, the publicity in the 1980s surrounding foreign acquisition activity in the United States created public concern over American firms being acquired by foreign entities, leading to a significant number of studies examining the wealth effects of foreign acquisitions and capital markets factors that affect acquisition activity. Since the early 1980s, the direction of the flow of cross-border acquisitions has shifted many times. During one time period, U.S. companies were acquiring foreign firms at a higher rate than they were being acquired, but by the end of the 1990s, foreign companies reversed this direction to become the predominant acquirer again. The cycle continues to this day, although of different durations. Studies done on acquisition activity between the U.S. and Britain (Vasconcellos et al., 1990), between the U.S. and Japan (Kish and Vasconcellos, 1993), between Canada and the U.S. (Vasconcellos and Kish, 1996), and between the U.S. and Europe (Vasconcellos and Kish, 1998) explore macroeconomic variables that contributed to this phenomenon.

43.1 Macroeconomic Factors

43.1.1 Favorable Acquisition Factors

Although there are a number of factors favoring acquisition activity, we focus on four of these factors: (1) exchange rates; (2) diversification; (3) economic conditions in the host country; and (4) technology and human resources within the acquiring firm.

43.1.1.1 Exchange Rates

One view on exchange rates revolves around the fact that while there seems to exist a relationship between exchange rates and acquisition activity, there is no evidence that a change in the exchange rate improves the position of foreign acquirers relative to their host counterparts. The argument is that when the host country's currency depreciates, the host country becomes a cheaper place for any firm to do business – foreign or domestic. Thus, the relationship between foreign acquisitions and exchange rates, contending that improved capital mobility facilitates equalized, risk-adjusted returns on international investments, is minimized. Another line of argument is that a depreciated host country's currency increases FDI in the host country's businesses. The reverse also holds true, i.e. if the host currency is strong, there should be a pause in the foreign acquisition of host firms and an upward trend in the home country's acquisitions of foreign firms.

43.1.1.2 Diversification

Given a firm's preferred risk-return position, international diversification by way of acquisition improves the risk-return tradeoff. This reasoning is based on the assumption that the covariance of returns across economies, even within the same industries, is likely to be smaller than within a single economy. The prospective acquiring company must first decide on its desired levels of risk and return. Only then should it attempt to identify countries, industries, and specific firms, which fall within its risk class. In addition, by acquiring an ongoing foreign concern, companies may be

able to circumvent tariff and nontariff barriers (i.e. quotas, voluntary restraint agreements, etc.), which attempt to protect the domestic industries and contribute to market segmentation. This action improves the risk-return tradeoff by lowering the level of unsystematic risk.

43.1.1.3 Current Economic Conditions in the Home Country

Adverse economic conditions in the home country, such as a slump, recession, or capital constraint may cause firms to concentrate on their domestic business while temporarily delaying strategic international moves. Once the economy rebounds, cross-border acquisitions are likely to again become a means for increasing demand and levels of diversification.

43.1.1.4 Acquisition of Technological and Human Resources

There are cases where a firm falls behind in the level of technological knowledge necessary to compete efficiently in its industry. If a firm is unable or unwilling to develop the required technology through research and development, it may attempt to acquire a foreign firm, which is technologically more advanced. Such an acquisition allows a firm to gain a foothold in a foreign country's market, and it may transfer the acquired technology back home, in order to strengthen its position in the domestic market. Some of the firms engaging in cross-border acquisitions are either transnational firms, or striving to become one. Transnational firms are able to behave like a local company in foreign markets, tapping into human and technological resources, while possessing the leverage of a larger, diversified entity. Indeed, this strategy provides significant diversification and allows the company to realize competencies in many markets.

43.1.2 Unfavorable Acquisition Factors

The factors discussed thus far generally tend to encourage firms to make cross-border acquisitions. In contrast, other variables that often serve to restrain cross-border movement include unavailability of information, inefficient management, monopolistic power, and government restrictions and regulations.

43.1.2.1 Unavailability of Information

The contention is that information about a prospective target firm is crucial in the decision-making process of an acquiring firm. Timely and accurate information include: current market share figures; comparisons with the competition; current sales; cash flow forecasts; and company specific strengths and weaknesses. However, foreign firms may not disclose these or other relevant figures. Thus, if the necessary information to make an accurate analysis is not available, the prospective acquiring firm may be forced to delay or discontinue its plans, even though the foreign firm appears to be an attractive target on the surface. Otherwise, failure to come up with an accurate analysis may prove harmful, or possibly devastating, to the acquiring firm. However, information effects are not always harmful, such as when the acquirer may be able to obtain information not available to other market participants.

43.1.2.2 Inefficient Management

The inefficiency argument centers on the acquiring firm being able to replace incompetent or inefficient management within the acquired firm in order to better utilize the firm's assets. The hope is that the new management will be able to increase the efficiency of the acquired firm and generate a higher return. A drawback of this action is the cost of replacing inefficient management. The negative aspects of the inefficiencies argument apply to the resistance that may materialize from the foreign managers who are left in place after the shake-up, emerging in the form of negative attitudes directed at the "outsiders" taking over the firm.

43.1.2.3 Monopolistic Power

Synergy arguments in defense of domestic or cross-border acquisitions are based on the economies of scale supposedly derived from horizontal mergers, economies of scope associated with vertical mergers, or the gains from acquiring monopolistic power. However, if monopolistic or even oligopolistic power is attained by a firm or a group of firms (a difficult position in most developed countries due to the threat of antitrust action), then entry to the industry becomes more difficult for any competitor, domestic or foreign. In addition, a monopolist is much more likely to resist a takeover. Some of the barriers to entry that make cross-border acquisitions difficult include: R&D outlays; capital expenditures necessary to establish a plant; and product differentiation, sometimes tied to large advertising expenditures.

43.1.2.4 Government Restrictions and Regulations

Most governments have some form of takeover regulations in place. In many instances, government approval is mandatory before acquisition by a foreign business can occur. In addition, government restrictions may exist on capital repatriations, dividend payouts, intra-company interest payments, and other remittances. Although these restrictions seem to be more prevalent in less developed countries, even in the developed markets, regulatory actions have been used to discourage acquisition activity. For example, the William's Amendment within the U.S. market increased the difficulty and costs of completing tender offers. The Tax Reform Act of 1986 has also been cited as a factor in the increased

acquisition transactions between U.S. sellers and foreign buyers. However, foreign buyers from countries with tax treaties with the host country are not subject to home taxes in repatriated earnings and, therefore, should be on equal footing with their host counterparts. Research in this area shows that most of the tax effects are industry-specific.

43.2 Microeconomic Factors

New relationships between the economic agents of different countries have come into existence with the ever-increasing globalization of markets. For example, the volume of cross-border mergers and acquisitions (M&A's) involving U.S. companies has increased in both the number of transactions and the dollar value for both net bidders and net targets. The exact motivations for cross-border M&A activity are many, including macroeconomic factors, firm-specific financial characteristics, corporate strategic moves, political motives, the possibility of a *good buy*, and/or the synergistic potential from the merged firms.

International merger and acquisition waves capture the attention of not only the business press but also of academia and policymakers. The effects of this merger-mania are felt by many (i.e. managers, stockholders, intermediaries, and consumers), and the dollar amounts are considerably high. To gain a better understanding of the characteristics of firms involved in the international market for corporate control, we now focus our attention on the firm-specific financial variables of both foreign companies and the host country's companies and the role that these variables have on the probability of the acquisition.

The composition of cross-border merger and acquisitions has changed over time. Contrary to the pattern in the 1970s, we have seen an increase in the relative proportion of U.S. targets and foreign acquirers in the 1980s and 1990s, with a slowdown in the first decade of the twentieth century. Among the most important factors in the past have attracted foreign firms to the U.S. market for corporate control are: (a) growth potential and accessibility to the U.S. market; (b) availability of high technology and highly skilled labor force; (c) relative easy access to financial markets; (d) undervaluation of some companies' stock; (e) relatively limited government intervention, and (f) currency fluctuations.

43.2.1 Undervaluation

The growing web of interdependencies in the global economy has developed new relationships between economic agents of different countries. Some existing international mergers and acquisitions research focuses primarily on wealth transfers. For instance, Doukas and Travlos (1988), besides offering an excellent review of this literature, contrasts the returns to shareholders from U.S. and non-U.S.-based firms expanding into foreign markets. Conn and Connell (1990) also include an extensive literature review of mergers and acquisitions within their empirical study of wealth transfers between the U.S. and British firms, as they expand into each other's markets.

Undervaluation revolves from the existence of product and service market imperfections that cause frictions in the global market (such as transaction costs and costs associated with barriers to entry), contributing to favor the acquisition of a company already operating. This is because the amount paid for an existing company, as compared to the replacement cost of its assets, more than compensates for the costs that could have been incurred had the foreign firm started with brand new facilities. Thus, in order to minimize the acquisition costs, foreign firms attempt to follow the same pattern of analysis as their domestic counterparts and search for undervalued and/or mismanaged companies as targets for their acquisitions. This is the basic premise of the empirical study undertaken by Gonzalez et al. (1998a, b), among others.

From the target firm's viewpoint, undervaluation is described as the likelihood of a host country's firm becoming a target increasing when the firm is perceived as being undervalued. Assuming that the takeover decision is motivated by the same stimuli that encourage firms to grow internally, a number of research studies utilize Tobin's "q" ratio as a predictor of takeover targets. High abnormal returns, experienced by acquirers before the merger, are consistent with a high "q" ratio, signaling to the companies that it is time to expand. Nevertheless, the conclusion is that the effect of the "q" ratio is not always significant and that these effects vary over time and across countries.

Furthermore, under the assumption that the financial market rewards well-managed firms, it is commonly interpreted that a "q" greater than 1 is a proxy for good management. Conversely, a ratio less than one is viewed as evidence of poor management. Thus, well-managed bidders benefit substantially from tender offers, but more so when they take over poorly managed targets. Well-managed targets benefit less from tender offers than poorly managed targets. The total takeover gain is highest for tender offers by well-managed bidders, which acquire poorly managed targets. This target undervaluation implies that there is an inverse relationship between the probability of a host country's company being acquired and the Tobin's q. The empirical research provides support for this view.

From the bidding firm's viewpoint, undervaluation is shown as the likelihood of a foreign firm bidding for a host country's company increasing when the firm is perceived as being overvalued. Therefore, the relationship between the ratio of market value to replacement cost of assets of foreign firms to the likelihood of these companies acquiring a host country's companies is supported (i.e. there is a positive relationship between the likelihood of a foreign firm bidding

for a host country's company and the ratio of market value to replacement cost of the foreign firm). Research results show the existence of direct relation between the possibility of a foreign firm bidding for a host country's firm and the Tobin's q of the overseas firm.

In sum, this research empirically validates undervaluation as a predictor of M&A activity within the international setting. The results support the existence of an inverse relationship between the probability of a host country's firm becoming a target of a foreign company and the Tobin's q ratio (i.e. undervalued host country's companies are more likely to be targets of foreign companies). This is consistent with the domestic market for corporate control.

If we relate these findings to Lang et al.'s (1989) conclusions from the domestic marketplace, then we observe positive abnormal returns for foreign companies upon the announcement of the foreign firms taking over a poorly managed host country's firms. A firm's overvaluation is proxied by a Tobin's q greater than 1. Lang et al. (1989) found positive abnormal returns when a firm with a Tobin's q greater than 1 (well-managed firm) acquired an undervalued company. Furthermore, foreign acquirers and host country's targets typically belong to the same industrial sectors. This can be interpreted as foreign companies reducing acquisition costs by acquiring undervalued firms as foreign firms trying to use their business knowhow to enhance the efficiency of the host country's targets.

Management inefficiency implies that the more inefficient is a firm's management, the greater is the probability of the firm becoming a target. Examples of variables used (in addition to the Tobin's q) to gauge management efficiency are the return on equity and sales growth. When the management is inefficient, both variables tend to show a negative relationship with the probability of an acquisition. Management inefficiency complements undervaluation reasoning. This interpretation is based on the premise that management fails to use the resources of the company up to their full potential. Thus, management inefficiency implies the existence of an inverse relationship between the ratio return on equity and growth and also the probability of the host country's company becoming a target of foreign firm. Therefore, the low return on equity and growth are manifestations of low quality management and are supported in the literature, implying that the probability that a host country's company will be taken over by a foreign firm is higher in case of greater inefficiency of the management of the domestic company.

43.2.2 Synergy Hypothesis

Much of the finance and accounting literature analyzing merger and acquisition activity is focused on the existence of synergy as a source of takeover gains within the domestic marketplace. Examples of the synergy identified that can transcend international borders include economies of scale, improved production techniques, increased market share, and more profitable use of existing assets. This suggests the existence of a direct relationship between the perceived degree of *ex-ante* synergy and the number of host country's firms acquired by foreign companies. The possibility of obtaining economies of scale, improving production techniques, increasing market share, and otherwise squeezing more profits out of existing assets are major assumptions made by the proponents of the effects from synergy. Before a merger, firms are assumed to be operating at levels of asset utilization that fall short of achieving their true potentials. Thus, the management of the bidding company could improve the performance of both the target and the expanded firm, whether on the domestic or international level.

In an extensive literature review of the sources of gains in mergers and acquisitions, Jensen and Ruback (1983) document support for the gains to the target firms' shareholders. The basic assumption within their review is that shareholders play a passive role in any takeover activity, relying on the existence of good management who, through sound investment decisions, will be able to maximize the shareholders' wealth. The consensus within their review of studies shows that the stock price of the target firm goes up at the time surrounding the announcement date. Moreover, the majority of the empirical studies of the takeover gains rely upon event study methodology to conclude that synergy is one of the main motives behind merger and acquisition activity. But event studies are primarily a measure of the reaction of a particular economic variable (e.g. stock prices) to the event of interest (e.g. the merger or acquisition announcement) measured *ex-post*. In addition, this methodology often impairs the distinction among alternative sources of gains. In other words, this methodology is not able to identify which components of the present value of net cash flows have changed.

The fact that these studies look at the efficiency gains from mergers and acquisitions (i.e. via synergy) *ex-post* might be impairing their ability to disentangle the true gains from synergy from the existence of market imperfections. Another limitation is that the event study methodology fails to account for the long-term effects of the takeover. Therefore, it is very difficult to distinguish the real sources of gains. An alternative *ex-ante* methodology is that synergy in mergers is measured by adding the acquisition premium to the difference between replacement costs and market value of the target firm (i.e. Tobin's q).

Relying on the relationship between the merger premium and the extent that replacement costs exceeds market value, a proxy successfully used the finance literature tests the effect of synergy. To measure the existence of *ex-ante* synergy, literature relies on the relationship between market value and replacement cost of the target assets. This

difference is then related to the premium paid in the takeover transaction. Thus, synergy shows up as a direct relationship between the perceived degree of *ex-ante* synergy and the number of host country's targets of foreign acquisitions. Assuming that the market for corporate control is competitive, a change in value of the firm is equal to the difference between the replacement cost of the assets of the target firm and the market value of those assets, plus the premium paid in the acquisition or merger.

Although synergy is a factor in many but not all merger activities, it is only one of the many hypotheses used to explain all merger activity. Other related merger hypotheses include management inefficiency, goodwill, and barriers to entry. For example, foreign companies often acquire a host country's companies to get around market frictions that might increase the cost of doing business in the host country. Empirical studies document the relationship between merger and acquisition activity and the presence of frictions in the market as proxied by the existence of goodwill and barriers to entry in a particular industry. Typically, the degree of goodwill and barriers to entry show a direct relationship with the probability of acquisition. One factor used to proxy goodwill is advertising expenses. The documented trend is that the higher the proportion of advertising expenses to net sales, the larger the number of customers that have some knowledge about the product or service of the firm. Alternatively, the proportion of research and development expenses to net sales is used as a proxy for barriers to entry. The higher the proportion of research and development expenses to net sales in a particular industry, the more difficult it is to enter in the industry. Thus, there is a direct relationship between the ratio of research and development expenses to net sales of a host country's firms and the probability of these firms being a target of an overseas company. But the results are not conclusive as to what is the impact of barriers to entry and goodwill in the probability of a host country's company becoming a target. Thus, it appears that the foreign firms acquired undervalued host country's companies based on what these overseas acquirers think they can put in play to improve the operations of the host firms and not necessarily on what the host companies offer to these foreign companies in terms of reducing barriers to entry or the existence of an already established customer base.

43.2.3 Maximizing the Value of the Firm

Under the assumption that the goal of corporate managers is the maximization of shareholders' wealth, the process of cross-border mergers and acquisitions flows from the neoclassical theoretical framework of maximization of the value of the firm. If the acquisition of a host country's company is a project with a net present value larger than zero, then there is an increase in the shareholders' wealth of the acquiring company. For instance, the empirical analysis by Vasconcellos et al. (1990), using a capital budget framework, measures the feasibility of a proposed foreign acquisition. Although their research was carried out on the influence of financial variables (used in the capital budgeting process) on the difference between American acquisitions of British firms and British acquisitions of American firms, some of these findings can be generalized for all cross-border M&A activity. For example, the exchange rate has a significant positive impact on the acquisition differential. In other words, foreign firms may acquire a host country's firms because of the relatively lower foreign currency value of the host country's currency (the host country's currency was "cheap"). The Kish and Vasconcellos (1993) study of cross-border acquisitions between the United States and Japan conclude that the stock prices and the costs of debt financing are the major contemporaneous causal factors; whereas exchange rates only had significance as a predictor of trends in acquisitions. Thus, generalities to fit all situations do not appear to exist. Most of the companies involved in cross-border M&As establish a sort of acquisition screening. This screening process involves country-specific and firm-specific screening variables (i.e. per capita GDP, market share of the target, etc.). The general conclusion is that the internationalization of the firm is a value-enhancing phenomenon.

The net present value (NPV) analysis assumes that the managers of the foreign firms bidding for the host country's companies decide to make the acquisition only when the decision has a positive impact on the shareholders' wealth of the foreign company. The net present value criteria assume a positive relationship between the factors affecting the NPV criterion and the likelihood of a foreign firm acquiring a host country's company. Another frequently argued view is that a relatively large and stable ("mature") host country's companies are more likely to go overseas than the average host's firms. Thus, the mature firm argument states that a host country's bidders in the cross-border merger and acquisition market are more likely to be mature firms.

Cross border M&A research start from the assumption that in the international market for corporate control, firms decide about an acquisition project using essentially the same decision-making framework that the firms would use for internal projects. Research supports the net present value approach and the assumption that the management of the foreign firm will undertake projects that have a positive impact on the wealth of its shareholders. The empirical research shows the existence of a positive relationship between the factors affecting the NPV criterion and the likelihood of a foreign firm acquiring a host country's firms.

Foreign firms also seem to be more likely to acquire a host country's companies with high debt capacity. A substantial debt capacity can be utilized to reduce the cost of the acquisition through debt financing at relatively low cost, whereas a high debt to equity ratio could increase the cost of new debt financing. Foreign firms are more likely to acquire a host country's companies with relatively high liquidity, as evidenced by the importance of the current ratio in the literature. In addition, host country's companies with relatively low price of stock to earnings are more probable to be acquired, serving as evidence that the managers of foreign companies acquiring host country's companies make their merger and/or acquisition decisions pursuing the maximization of the foreign companies shareholders' wealth.

In addition to examining the financial characteristics of the host country's targets from cross-border M&A, the same analysis for the host country's bidders in the global takeover market has been summarized. The reasons for a host country's FDI have been widely discussed in the literature. The motivations leading to host country's FDI include product market imperfections, institutional imperfections (i.e. differentials in tax laws), and limitations of the domestic market.

Jensen (1988) argues that firms with free cash flows will be likely bidders in the takeover market. Thus, mature firms in a host country are more likely to be bidders in the cross-border M&A market. Normally, a company follows a life cycle that is closely connected to product line development. A mature firm has a relatively stable financial profile and may face two options: to become "better" or to get "bigger" In order to become "bigger," these companies may attempt to go overseas.

The following financial variables proxy for identifying mature companies relative to the industry: net sales growth, size of total assets, price-earnings ratio, and free cash flow. There is an inverse relationship between both the growth and the price–earnings ratio of a host country's firm and the probability of this firm becoming a bidder in the global market for corporate control. Furthermore, there is direct association between both the size and free cash flow of a host country's company relative to the industry and the likelihood of this company becoming a bidder for a foreign firm. In addition, foreign firms with a "Tobin's q" greater than 1 are more likely to acquire a host country's companies. This is consistent with Jensen's (1988) conclusions. Relatively high "Tobin's q" firms may have enough resources to invest in the acquisition of other firms. The exchange rate does not have a strong impact on the probability of acquisition of a host country's company. For example, a very strong dollar during the first half of the 1980s and a weak dollar the second half failed to impact the number of U.S. companies acquired or acquiring in that they were on average the same. There are alternative (and not mutually exclusive)

explanations for the difference on the importance attributed to the exchange rate. First, most of the studies found in the literature examining the difference between the number of host country's acquisitions of foreign companies versus the number of foreign acquisitions of host country's firms report inconsistent results. Second, the exchange rate could affect the timing of the acquisition but not the acquisition decision itself. The other possibility is that there are different time periods being studied. Also found was that the foreign firms have a relatively high return on equity when compared to the industry average. Since return on equity is used as a proxy for management efficiency, the conclusion is that foreign companies with above average efficiency in their countries have a higher likelihood of acquiring a host country's firms.

The combined results on "Tobin's q" for the host country's targets and foreign bidders mirror the domestic case of mergers and acquisitions. That is, high "Tobin's q" foreign bidders had positive abnormal returns when they acquired targets with "Tobin's q" < 1. Research supports the share-holders' wealth maximization theory as applied to the investment decision of whether or not to acquire a host country's companies. Finally, the host country's companies going overseas are "mature" companies with large amounts of assets, considerable free cash flows, and low growth. The fact that the host country's companies acquiring foreign companies have an average low price to earnings ratio may be interpreted as a move of the management of these host country's companies to attempt to maximize its shareholders' wealth by signaling to the market that the increase in globalization of the company's operations is a risk reduction event due to diversification.

43.3 An Analytical View of Cross-Border Mergers and Acquisitions

The feasibility of a foreign acquisition can be evaluated first like any other project, with specific attention to peculiar characteristics. Capital budgeting analysis can be applied to determine whether the NPV of the acquisition is positive. Consider the following capital budgeting framework, as applied to a foreign acquisition:

$$\text{NPV}_{\text{FA}} = -I_{\text{FA}} + \sum_{t=1}^{n} \frac{\text{CF}_{\text{FA},t}}{(1 + k_{\text{FA}})^t} + \frac{\text{SV}_{\text{FA},n}}{(1 + k_{\text{FA}})^n} \quad (43.1)$$

where NPV_{FA} is the net present value of a foreign acquisition; I_{FA} the initial outlay of a foreign acquisition; k_{FA} the required return on the foreign acquisition; CF_{FA} the cash flows to the acquirer; SV the salvage value to the acquirer; t the = time period and n the number of periods in which the project is expected to exist.

As with any project, the variables above should incorporate any tax implications so that the net present value reflects after-tax cash flows. In addition, all cash flows should be measured from the acquirer's perspective and in the acquirer's home currency.

Breaking the general NPV equation into its components can identify the factors that influence a firm's attraction to a prospective foreign acquirer. The following discussion identifies the specific factors, which affect a foreign acquisition's initial outlay, periodic cash flows, and salvage value. The initial outlay (I_{FA}) can be broken down into three components, as shown below:

$$I_{FA} = E_h + D_h + D_f(ER_f) \qquad (43.2)$$

where E_h the equity in the home currency; D_h borrowed funds in the home currency; D_f the borrowed funds in the foreign currency; and $ER_{f,\,t}$ the exchange rate of foreign currency at the time the foreign funds were borrowed.

To measure the entire initial outlay in terms of the home currency, any foreign funds borrowed by the acquiring firm must be translated into the home currency. Moreover, some firms may cover the entire initial outlay from any one of the above components.

The relevant cash flows in the analysis of cross-border mergers and acquisitions are those received by the acquiring firm. These cash flows are determined by: (1) the after-tax foreign cash flows generated; (2) the percentage of those after-tax cash flows to be remitted to the acquirer; and (3) the exchange rates at the time the after-tax foreign cash flows are remitted. Then, the after-tax cash flows received by the acquiring firm can be described as:

$$CF_{FA,t} = (CF_{f,t})(1 - R_{f,t})(ER_{f,t}) \qquad (43.3)$$

where $CF_{f,t}$ is the foreign cash flows generated during period t; $R_{f,t}$ the proportion of cash flows retained by the (then) foreign subsidiary to support future operations; and $ER_{f,t}$ the exchange rate of the foreign currency at the time cash flows are remitted to the acquiring firm.

The salvage value from the acquirer's perspective as of time $n (SV_{FA,n})$ is determined by the anticipated foreign market value of the acquired business at time $n (MV_{f,n})$, and the prevailing exchange rate at the time of the planned sale, as described below:

$$SV_{FA,n} = (MV_{f,n})(ER_{f,n}) \qquad (43.4)$$

Note that the foreign value may represent a liquidation value or a going concern value, whichever is likely to be higher.

Integrating the detailed expressions for the initial outlay, periodic cash flows, and salvage value, a comprehensive expression for the NPV analysis of a foreign acquisition can be written as follows:

$$\begin{aligned}
NPV_{FA} &= -I_{FA} + \sum_{t=1}^{n} \frac{CF_{FA,t}}{(1+k_{FA})^t} + \frac{SV_{FA,n}}{(1+k_{FA})^n} \\
&= -[E_h + D_h + D_f(ER_f)] \\
&\quad + \sum_{t=1}^{n} \frac{[(CF_{f,t})(1 - R_{f,t})(ER_{f,t})]}{(1+k_{FA})^t} \frac{[(MV_{f,n})(ER_{f,n})]}{(1+k_{FA})^n}
\end{aligned}$$
$$(43.5)$$

When expressed as in Equation 43.5, the capital budgeting approach provides a valuable framework for explaining the influence of several factors regarding the feasibility of foreign acquisitions.

In conclusion, the phenomenon of cross-border mergers and acquisitions has shown vitality in the last two decades and the trend appears set to continue in the new century. For example, the UNCTAD's *World Investment Report, 2000* reported that the overall value of the flow of cross-border mergers and acquisitions was $151 billion in 1991 and increased to $720 billion in 1999 (UNCTAD, 2000). In addition, the annual growth rates of these flows are shown to be 26.4% for 1986–1990, 23.3% for 1991–1995, and 46.9% for 1996–1999. Moreover, the quickly evolving single European market in the late 1980s and early 1990s encouraged many non-European firms to establish a presence in Europe before the barriers to entry intensified. Consequently, by the mid-1990s U.S. FDIs in the European Union increased by approximately 200% from the early 1980s. In general terms, empirical analysis supports the fact that both a host country's and the foreign country's stock prices are a major causal factor that influence cross-border mergers and acquisitions. Bond yields are also shown to be major causal factors. This implies that bond yields may be one of the final negotiating points in the decision to consummate an acquisition. Finally, the exchange rate does not consistently acquire significance for all countries. Thus, the exchange rate can only serve as a predictor of trends in acquisitions.

Shin-Huei Wang

Abstract

Jump diffusion processes have been used in modern finance to capture discontinuous behavior in asset pricing. Various jump diffusion models are considered in this chapter. Also, the applications of jump diffusion processes on stocks, bonds, and interest rate are discussed.

Keywords

Affine jump diffusion model • ARCH/GARCH jump diffusion model • Autoregressive jump process model • Bernoulli jump process • Black–Scholes model • Conditional jump dynamics • Gauss–Hermite jump process • Jump diffusion process • Jump diffusion with conditional heteroskedasticity • Mixed-jump process

44.1 Introduction

In contrast to basic insights into continuous-time asset-pricing models that have been driven by stochastic diffusion processes with continuous sample paths, jump diffusion processes have been used in finance to capture discontinuous behavior in asset pricing. As described in Merton (1976), the validity of Black–Scholes formula depends on whether the stock price dynamics can be described by a continuous-time diffusion process whose sample path is continuous with probability 1. Thus, if the stock price dynamics cannot be represented by stochastic process with a continuous sample path, the Black–Scholes solution is not valid. In other words, as the price processes feature big jumps, i.e. not continuous, continuous-time models cannot explain why the jumps occur, and hence not adequate. In addition, Ahn and Thompson (1986) also examined the effect of regulatory risks on the valuation of public utilities and found that those "jump risks" were priced even though they were

uncorrelated with market factors. It shows that jump risks cannot be ignored in the pricing of assets. Thus, a "jump" stochastic process defined in continuous time, and also called as "jump diffusion model" was rapidly developed.

The jump diffusion process is based on Poisson process, which can be used for modeling systematic jumps caused by surprise effect. Suppose we observe a stochastic process S_t, which satisfies the following stochastic differential equation with jump:

$$\mathrm{d}S_t = a_t\mathrm{d}t + \sigma_t\mathrm{d}W_t + \mathrm{d}J_t, \ t \geq 0 \qquad (44.1)$$

where $\mathrm{d}W_t$ is a standard Wiener process. The term $\mathrm{d}J_t$ represents possible unanticipated jumps, and which is a Poisson process. As defined in Gourieroux and Jasiak (2001), a jump process $(J_t, t \ R^+)$ is an increasing process such that

(i) $J_0 = 0$,
(ii) $P[J_{t+\mathrm{d}t} - J_t = 1 | J_t] = \lambda_t\mathrm{d}t + o(\mathrm{d}t)$,
(iii) $P[J_{t+\mathrm{d}t} - J_t = 0 | J_t] = 1 - \lambda_t\mathrm{d}t + o(\mathrm{d}t)$,

where $o(\mathrm{d}t)$ tends to 0 when t tends to 0, and λ_t, called the intensity, is a function of the information available at time t.

Furthermore, since the term $\mathrm{d}J_t$ is part of the unpredictable innovation terms we make $E[\Delta J_t] = 0$, which has zero mean during a finite interval h. Besides, as any predictable part of the jumps may be can be included in the drift component α_t, jump times $\tau_j, j = 1, 2,....$ vary by some discrete and random amount. Without loss of generality, we assume that there are k possible types of jumps, with size a_i, $i = 1, 2, L$, and the jumps occur at rate λ_t that may depend on the latest observed S_t. As soon as a jump occurs, the jump type is selected randomly and independently. The probability of a jump of size a_i, occurring is given by p_i. Particularly, for the case of the standard Poisson process, all jumps have size 1. In short, the path of a jump process is an increasing stepwise function with jumps equal to 1 at random rate $D_1, D_2,\ldots, D_t,\ldots,$.

Related research on the earlier development of a basic Poisson jump model in finance was by Press (1967). His model can be motivated as the aggregation of a number of price changes within a fixed-time interval. In his paper, the Poisson distribution governs the number of events that result in price movement, and the average number of events in a time interval is called intensity. In addition, he assumes that all volatility dynamics is the result of discrete jumps in stock returns and the size of a jump is stochastic and normally distributed. Consequently, some empirical applications found that a normal Poisson jump model provides a good statistical characterization of daily exchange rate and stock returns. For instance, using Standard and Poor's 500 futures options and assuming an underlying jump diffusion, Bates (1991) found systematic behavior in expected jumps before the 1987 stock market crash. In practice, by observing different paths of asset prices with respect to different assets, distinct jump diffusion models were introduced into literature by many researchers. Therefore, in this chapter, we will survey various jump diffusion models in current literature as well as estimation procedures for these processes.

44.2   Mixed-Jump Processes

The total change in asset prices may be comprised of two types of changes:

Normal vibrations caused by marginal information events satisfying a local Markov property and modeled by a standard geometric Brownian motion with a constant variance per unit time. It has a continuous sample path.

Abnormal vibrations caused by information shocks satisfying an antipathetical jump process defined in continuous time, and modeled by a jump process, reflecting the nonmarginal impact of the information.

Thus, there have been a variety of studies that explain too many outliers for a simple, constant-variance log-normal distribution of stock price series. Among them, Merton (1976) and Tucker and Pond (1988) provide a more thorough

discussion of mixed-jump processes. Mixed-jump processes are formed by combining a continuous diffusion process and a discrete-jump process and may capture local and nonlocal asset price dynamics.

Merton (1976) pioneered the use of jump processes in continuous-time finance. He derived an option pricing formula as the underlying stock returns are generated by a mixture of both continuous and the jump processes. He posited stock returns as

$$\frac{\mathrm{d}S}{\mathrm{S}} = (\alpha - \lambda k)\mathrm{d}t + \sigma\mathrm{d}Z + \mathrm{d}q \qquad (44.2)$$

where S is the stock price, α the instantaneous expected return on the stock, σ^2 the instantaneous variance of the stock return conditional on no arrivals of "abnormal" information, $\mathrm{d}Z$ the standardized Wiener process, q the Poisson process assumed independent of $\mathrm{d}Z$, λ the intensity of the Poisson process, $k = \varepsilon(\tilde{Y} - 1)$, where $\tilde{Y} - 1$ is the random variable percentage change in stock price if the Poisson event occurs; ε is the expectation operator over the random variable Y. Actually, Equation 44.1 can be rewritten as

$$\frac{\mathrm{d}S}{\mathrm{S}} = (\alpha - \lambda k)\mathrm{d}t + \sigma\mathrm{d}Z$$
$$\text{if the Poisson does not occur} \qquad (44.3)$$
$$= (\alpha - \lambda\mathrm{k})\mathrm{d}t + \sigma\mathrm{d}Z + (Y - 1),$$
$$\text{if the Poisson occurs}$$

Therefore, the option return dynamics can be rewritten as

$$\frac{dW}{W} = (\alpha_w - \lambda k_w)\mathrm{d}t + \sigma_w\mathrm{d}Z + \mathrm{d}q_w \qquad (44.4)$$

Most likely, α_w is the instantaneous expected return on the option, σ_ω^2 is the instantaneous variance of the stock return conditional on no arrivals of "abnormal" information, q_w is an Poisson process with parameter λ assumed independent of $\mathrm{d}Z$, $k_w = \varepsilon(Y_w - 1)$, $(Y_w - 1)$ is the random variable percentage change in option price if the Poisson event occurs, ε is the expectation operator over the random variable Y_w. The Poisson event for the option price occurs if and only if the Poisson event for the stock price occurs. Further, define the random variable, X_n, which has the same distribution as the product of n independently and identically distributed random variables. Each of n independently and identically distributed random variables has the identical distribution as the random variable Y described in Equation 44.1. As a consequence, by the original Black–Scholes option pricing formula for the no-jump case, $W(S, \tau; E, r, \sigma^2)$, we can get the option price with jump component

$$F(s, \tau) = \sum_{n=1}^{\infty} \frac{\mathrm{e}^{-\lambda\tau}(\lambda\tau)^n}{n!} [\varepsilon_n\{W(SX_n\mathrm{e}^{-\lambda k\tau,\tau}; E, \sigma^2, r)\}] \quad (44.5)$$

Generally speaking, W satisfies the boundary conditions of partial differential equation (see Oksendal, 1988), and can be rewritten as a twice continuously differentiable function of the stock price and time, $W(t) = F(S, t)$. Nevertheless, Equation 44.5 still not only holds most of the attractive features of the original Black–Scholes formula such as being regardless of the investor preferences or knowledge of the expected return on the underlying stock, but also satisfies the Sharpe–Linter Capital Asset Pricing model as long as the jump component of a security's return is uncorrelated with the market. In other words, the mixed-jump model of Merton uses the CAPM to value options written on securities involving jump processes.

Also, Tucker and Pond (1988) empirically investigated four candidate processes (the scaled-t distribution, the general stable distribution, compound normal distribution, and the mixed-jump model) for characterizing daily exchange rate changes for six major trading currencies from the period 1980 to 1984. They found that the mixed-jump model exhibited the best distributional fit for all six currencies tested. Akgiray and Booth (1988) also found that the mixed-diffusion jump process was superior to the stable laws or mixture of normals as a model of exchange rate changes for the British pound, French franc, and the West German mark relative to the U.S. dollar. Thus, both theoretical and empirical studies of exchange rate theories under uncertainty should explicitly allow for the presence of discontinuities in exchange rate processes. In addition, the assumption of pure diffusion processes for exchange rates could lead to misleading inferences due to its crude approximation.

44.3 Bernoulli Jump Process

In the implementation of empirical works, Ball and Torous (1983) provide statistical evidence with the existence of lognormally distributed jumps in a majority of the daily returns of a sample of NYSE-listed common stocks. The expression of their Poisson jump diffusion model is as Equation 44.1, and jump size Y has posited distribution, $\ln Y \sim N(\mu, \delta^2)$.

Ball and Torous (1983) introduced the Bernoulli jump process as an appropriate model for stock price jumps. Denote X_i as the number of events that occur in subinterval i and independent distributed random variables. By stationary independent increment assumption,

$$N = \sum_{i=1}^{n} X_i,$$

where N is the number of events that occur in a time interval of length t. Besides, define $h = t/n$ for any arbitrary integer n

and divide $(0, t)$ into n equal subintervals each of length h. Thus, X_i satisfies

$$
\begin{aligned}
&\Pr[X_i = 0] = 1 - \lambda h + O(h) \\
&\Pr[X_i = 1] = \lambda h + O(h) \ \text{ for } i = 1, 2, ..., n \\
&\Pr[X_i > 1] = O(h)
\end{aligned}
$$

For large n, X_i has approximately the Bernoulli distribution with parameter $\lambda h = \lambda t/n$. As a result, N has the binomial distribution, approximately, i.e.

$$\Pr[N = k] \cong \binom{n}{k}\left(\frac{\lambda t}{n}\right)^k \left(1 - \frac{\lambda t}{n}\right)^{n-k} k = 0, \ 1, \ 2, \ ..., n.$$

Now, assume that t is very small, they can approximate N by the Bernoulli variate X defined by

$$
\begin{aligned}
P[X = 0] &= 1 - \lambda t, \\
P[X = 1] &= \lambda t.
\end{aligned}
$$

The advantage of the Bernoulli$\neq$ jump process is that more satisfactory empirical analyses are available. The maximum likelihood estimation can be practically implemented and the unbiased, consistent, and efficient estimators that attain the Cramer–Rao lower bound for the corresponding parameters. Moreover, the statistically most powerful test of the null hypothesis $\lambda = 0$ can be implemented. Obviously, a Bernoulli jump process models information arrivals and stock price jumps. This shows that the presence of a jump component in common stock returns can be possessed well. As a consequence, Vlaar and Palm (1993) combined the GARCH (1,1) and Bernoulli jump distribution to account for skewness and leptokurtosis for weekly rates of the European Monetary System (EMS). Das (2002) considered the concept of Bernoulli approximation to test the impact of Federal Reserve actions by Federal Funds' rate as well. (See Section 43.9.2 and Section 43.5, respectively).

44.4 Gauss–Hermite Jump Process

To ensure the efficiency properties in valuing compound option, Omberg (1988) derived a family of jump models by employing Gauss–Hermite quadrature.

Note that $t = 0$ and $t = T$ are the current time and expiration date of the option, respectively, and $\Delta t = T/N$. Consider a compound option that can only be exercised at the N interval boundaries $t_k = T - k\Delta t$, $k = 0,..., N$. Let $C_k(S)$ be the value of the compound option at time t_k, the current value of the compound option is then $C_N(S)$; the value of an actual contingent claim with optimal exercise

possible at any time is $\lim N \to C_N(S)$. The compound option can be recursively valued by

$$C_{k+1}(S) = \max\{EV_{k+1}, \, e^{-r}\Delta t E[C_k(S_k;S)]\},$$

where EV_{k+1} is the immediate exercise value at time t_{k+1}. Since $S(t)$ is an unrestricted log-normal diffusion process from t_k to t_{k+1},

$$E[C_k] = \int_{-\infty}^{\infty} \phi(z)C_k\left(Se^{\mu'\Delta t + z\sigma\sqrt{(\Delta t)}}\right)dz, \qquad (44.6)$$

where z is an independent sample from a normal distribution with mean zero and variance one, $\phi(z)$ is its density function, and $\mu' = r - \sigma^2/2$ for a risk-neutral valuation. A jump process approximation to the above with n jumps takes the form

$$E[C_k] \cong \sum_{j=1}^{n} p_j C_k(Se^{\mu}j), \, p_j \leq 0 \text{ for } j = 1, ..., n,$$

$$\sum_{j=1}^{n} p_j = 1, \, u_j = \mu'\Delta t + z_j\sigma\sqrt{(\Delta t)}$$

So, Omberg (1988) considers to use Gaussian integration to approximate an integration of the form as in Equation 44.6. For example, for the intergral,

$$I = \int_a^b w(x)f(x)dx,$$

we can approximate this equation by a weighted average of the function $f(x)$ at n points $\{x_1, ..., x_n\}$. Let $\{w_i\}$ and $\{x_j\}$ are selected to maximize the degree of precision m^*, which is a integration rule, i.e. if the integration error is zero for all polynomials $f(x)$ of order m^* or less. $\{P_j(x)\}$ is the set of polynomials with respect to the weighting function $w(x)$,

$$\int_a^b w(x)P_i(x)P_j(x)dx = 0, \text{ for } i \neq j,$$

$$\int_a^b w(x)P_j^2(x)dx = \gamma_j \neq 0, \text{ for } i = j,$$

Thus, the optimal evaluation points $\{X_j\}$ are the n zeros of $P_n(x)$ and the corresponding weights $\{w_j\}$ are

$$w_j = \frac{-(a_{n+1,n+1}/a_{n,n})\gamma_n}{P'_n(x_j)P_{n+1}(x_j)} > 0.$$

The degree of precision is $m^* = 2n - 1$. If the weighting function $w(x)$ is symmetric with regard to the midpoint of the interval $[a, b]$, then $\{x_j\}$ and $\{w_j\}$ are the Gaussian evaluation points $\{x_j\}$ and weights $\{w_j\}$, respectively. Particularly, the above procedure is called Gauss–Hermite quadrature to approximate the integration problem. What is shown in Omberg (1988) is the application of Gauss–Hermite quadrature to the valuation of a compound option, which is a natural way to generate jump processes of any order n that are efficient in option valuation. Thus, the Gauss–Hermite jump process arises as an efficient solution to the problem of replicating a contingent claim over a finite period of time with a portfolio of assets. With this result, he suggested the extension of these methods to option valuation problems with multiple state variables, such as the valuation of bond options in which the state variables are taken to be interest rates at various terms.

44.5 Jumps in Interest Rates

Cox et al. (1985a) proposed an influential paper that derived a general equilibrium asset pricing model under the assumption of diffusion processes, and analyzed the term structure of interest rate by it. Ahn and Thompson (1988) applied Cox, Ingersoll, and Ross's methodology to their model, which is driven by jump diffusion processes, and investigated the effect of jump components of the underlying processes on the term structure of interest rates. They differ from the model of Cox et al. (1985b) when they consider the state variables as jump diffusion processes. Therefore, they suggested that jump risks may have important implications for interest rate, and cannot be ignored for the pricing of assets. In other words, they found that Merton's (1973) multi-beta CAPM does not hold in general due to the existence of jump component of the underlying processes on the term structure of interest rate. Also, Breeden's single consumption beta does not hold, because the discontinuous movements of the investment opportunities cannot be fully captured by a single consumption beta. Moreover, in contrast with the work of Cox et al. (1981) providing that the traditional expectations theory is not consistent with the equilibrium models, they found that traditional expectations theory is not consistent with the equilibrium models as the term structure of interest rate is under the jump diffusion process, since the term premium is affected by the jump risk premiums. Das (2002) tested the impact of Federal Reserve actions by examining the role of jump-enhanced stochastic processes in modeling the Federal Funds rate. This research illustrated that compared to the stochastic processes of equities and foreign exchange rates, the analytics for interest rates are more complicated. One source of analytical complexity considered in modeling interest rates with jumps is mean reversion. Allowing for mean reversion included in jump diffusion processes, the process for interest rates employed in that paper is as follows

$$dr = k(\theta - r)dt + \upsilon dz + J d\pi(h), \qquad (44.7)$$

which shows interest rate has mean-reversing drift and two random terms, a pure diffusion process and a Poisson process with a random jump J. In addition, the variance of the diffusion is υ^2, and a Poisson process π represents the arrival of jumps with arrival frequency parameter h, which is defined as the number of jumps per year. Moreover, denote J as jump size, which can be a constant or with a probability distribution. The diffusion and Poisson processes are independent of each other as well as independent of J.

The estimation method used here is the Bernoulli approximation proposed in Ball and Torous (1983). Assuming that there exists no jump or only one jump in each time interval, approximate the likelihood function for the Poisson–Gauss model using a Bernoulli mixture of the normal distributions governing the diffusion and jump shocks.

In discrete time, Equation 44.7 can be expressed as follows:

$$\Delta r = k(\theta - r)\Delta t + \upsilon \Delta z + J(\mu, \gamma^2)\Delta\pi(h),$$

where υ^2 is the annualized variance of the Gaussian shock, and Δz is a standard normal shock term. $J(\mu, \gamma^2)$ is the jump shock with normal distribution. $\Delta\pi(q)$ is the discrete-time Poisson increment, approximated by a Bernoulli distribution with parameter $q = h\Delta t + O(\Delta t)$, allowing the jump intensity q to depend on various state variables conditionally. The transition probabilities for interest rates following a Poisson–Gaussian process are written as (for s > t):

$$f[r(s)r(t)] = q \exp\left(\frac{-(r(s) - r(t) - k(\theta - r(t))\Delta t - \mu)^2}{2(\upsilon_t^2 \Delta t + \gamma^2)}\right)$$
$$\frac{1}{\sqrt{(2\pi(\upsilon_t^2 \Delta t + \gamma^2))}}$$
$$+ (1 - q) \exp\left(\frac{-(r(s) - r(t) - k(\theta - r(t))\Delta t)^2}{2\upsilon_t^2 \Delta t}\right)$$
$$\frac{1}{\sqrt{(\pi\upsilon_t^2 \Delta t)}},$$

where $q = h\Delta t + O(\Delta t)$. This is an approximation for the true Poisson–Gaussian density with a mixture of normal distributions. As in Ball and Torous (1983, 1985), by maximum-likelihood estimation, which maximizes the following function L,

$$L = \prod_{t=1}^{T} f[r(t + \Delta t)|r(t)],$$

we can obtain estimates that are consistent, unbiased, and efficient and attain the Cramer-Rao lower bound. Thus, they obtain the evidence that jumps are an essential component of interest rate models. Especially, the addition of a jump process diminishes the extent of nonlinearity although some research finds that the drift term in the stochastic process for interest rates appears to be nonlinear.

Johannes (2004) suggested the estimated infinitesimal conditional moments to examine the statistical and economic role of jumps in continuous-time interest rate models. Based on Johannes's approach, Bandi and Nguyen (2003) provided a general asymptotic theory for the full function estimates of the infinitesimal moments of continuous-time models with discontinuous sample paths of the jump diffusion type. Their framework justifies consistent nonparametric extraction of the parameters and functions that drive the dynamic evolution of the process of interest. (i.e. the potentially nonaffine and level dependent intensity of the jump arrival being an example). Particularly, Singleton (2001) provided characteristic function approaches to deal with the Affine jump diffusion models of interest rate. In the next section, we will introduce affine jump diffusion model.

44.6 Affine Jump Diffusion Model

For development in dynamic asset pricing models, a particular assumption is that the state vector X follows an affine jump diffusion (AJD). An affine jump model is a jump diffusion process. In general, as defined in Duffie and Kan (1996), we suppose the diffusion for a Markov process X is 'affine' if

$$\mu(y) = \theta + \kappa y$$
$$\sigma(y)\sigma(y)' = h + \sum_{j=1}^{N} y_j H^{(j)},$$

where $\mu: D \to R^n$ and $\sigma: D \to R^{n \times n}$, θ is $N \times 1$, κ is $N \times N$, h and $H^{(j)}$ are all $N \times N$ and symmetric. The X's may represent observed asset returns or prices or unobserved state variables in a dynamic pricing model, such as affine term structure models. Thus, extending the concept of 'affine' to the case of affine jump diffusions, we can note that the properties for affine jump diffusions are that the drift vector, 'instantaneous' covariance matrix, and jump intensities all have affine dependence on the state vector. Vasicek (1977) and Cox et al. (1985b) proposed the Gaussian and square root diffusion models which are among the AJD models in term structure literature. Suppose that X is a Markov process in some state space $D \subset R^n$, the affine jump diffusion is

$$dX_t = \mu(X_t)dt + \sigma(X_t)dW_t + dZt,$$

where W is an standard Brownian motion in R^n, $\mu: D \to R^n$, $\sigma: D \to R^{n \times n}$, and Z is a pure jump process whose jumps

have a fixed probability distribution υ on and arriving intensity $\{\lambda(X_t): t \geq 0\}$, for some $\lambda: D \rightarrow [0, \infty)$.

Furthermore, in Duffie et al. (2000), they suppose that X is Markov process whose transition semi-group has an infinitesimal generator of levy type defined at a bounded C^2 function $f: D \rightarrow R$ with bounded first and second derives by

$$\wp f(x) = f_x(x)\mu(x) + \frac{1}{2}tr[f_{xx}(x)\sigma(x)\sigma(x)^T] + \lambda(x).$$

It means that conditional on the path of X, the jump times of Z are the jump times of a Poisson process with time varying intensity $\{\lambda(X_s): 0 \leq s \leq t\}$, and that the size of the jump of Z at a jump time T is independent of $\{X_s: 0 \leq s \leq T\}$, and has the probability distribution υ. Consequently, they provide an analytical treatment of a class of transforms, including Laplace and Fourier transformations in the setting of affine jump diffusion state process.

The first step to their method is to show that the Fourier transform of X_t and of certain related random variables are known in closed form. Next, by inverting this transform, they show how the distribution of X_t and the prices of options can be recovered. Then, they fix an affine discount rate function $R: D \rightarrow R$. Depending on coefficients (K, H, L, ρ), the affine dependence of $\mu, \sigma\sigma^T, \lambda, R$ are determined, as shown in p. 1350 of Duffie et al. (2000). Moreover, for $c\ C^n$, the set of n-tuples of complex numbers, let $\theta(c) = \int_R{}^n \exp (c.z)dv(z)$. Thus, the "jump transform" θ determines the jump size distribution. In other words, the "coefficients" (K, H, l, θ) of X completely determine its distribution. Their method suggests a real advantage of choosing a jump distribution v with an explicitly known or easily computed jump transform θ. They also applied their transform analysis to the pricing of options. See Duffle et al. (2000). Furthermore, Singleton (2001) developed several estimation strategies for affine asset pricing models based on the known functional form of the conditional characteristic function (CCF) of discretely sampled observations from an affine jump diffusion model, such as LML-CCF (Limited-information estimation), ML-CCF (Maximum likelihood estimation), and GMM-CCF estimation, etc. As shown in his paper, a method of moments estimator based on the CCF is shown to approximate the efficiency of maximum likelihood for affine diffusion models.

44.7   Geometric Jump Diffusion Model

Using Geometric Jump Diffusion with the instantaneous conditional variance, V_t, following a mean reverting square root process, Bates (1996) showed that the exchange rate, S($/deutschemark (DM)) followed it:

$$dS/S = (\mu - \lambda\overline{k})dt + \sqrt{V}dZ + kdq$$
$$dV = (\alpha - \beta V)dt + \sigma_v\sqrt{V}dZ_v$$
$$\text{Cov}\,(dZ, dZ_v)$$
$$\text{Pr}\,(dq = 1) = \lambda dt$$
$$\ln\,(1 + k) \sim N\left(\ln\,(1 + \overline{k}) - \frac{1}{2}\delta^2,\ \delta^2\right),$$

where μ is the instantaneous expected rate of appreciation of the foreign currency, λ is the numbers of jumps in a year, k is the random percentage jump conditional on a jump occurring, and q is a Poisson counter with intensity λ.

The main idea of this model illustrated that skewed distribution can arise by considering nonzero average jumps. Similarly, it also discusses that excess kurtosis can arise from a substantial jump component. In addition, this geometric jump diffusion model can see a direct relationship between the magnitude of conditional skewness and excess kurtosis and the length of the holding period as well.

44.8   Autoregressive Jump Process Model

A theory of the distribution of stock returns was derived by Bachelier (1900) and expanded using the idea of Brownian motion by Osborne (1959). However, the empirical works generally concluded that the B-O model fits observed returns rather poorly. For example, a casual examination of transactions data shows that assumption of a constant interval between transactions is not strictly valid. On the other hand, transactions for a given stock occur at random times throughout a day which gives nonuniform time intervals Also, the notion of independence between transaction returns is suspect. Niederhoffer and Osborne (1966) showed that the empirical tests of independence using returns based on transaction data have generally found large and statistically significant negative correlation. Thus, it is reasonable to model returns as a process with random time intervals between transaction and serial correlation among returns on individual trades. Accordingly, an auto-regressive jump process that models common stock returns through time was proposed by Oldfield et al. (1977). This model consists of a diffusion process, which is continuous with probability 1 and jump processes, which are continuous with probability 1. The jump process is assumed to operate such that a jump occurs at each actual transaction, and allows the magnitudes of jumps to be auto-correlated. In addition, the model relies on the distribution of random time intervals between transactions. They suppose the dollar return of a common stock over a holding period of length s is the result of a process, which is a mixture process composed of a continuous and jump process,

$$\frac{dP}{P} = \alpha dt + \beta dW + zd\pi, \qquad (44.8)$$

where P stands for share price, dW is the increment of a Wiener process with zero mean and unit variance, z is the percent change in share price resulting from a jump, $d\pi$ is a jump process (when $d\pi = 1$, a jump occurs; when $d\pi = 0$, no jump occurs) and $d\pi$ and dW are assumed to be independent. Jump amplitude is independent of $d\pi$ and dW, but jumps may be serially correlated, s is the elapsed time between observed price P_{t+s} and P_t. The number of jumps during the interval s is N, and $Z(i)$ are the jump size where $Z(0) = 1$ and $Z(i) \geq 0$ for $i = 1, \ldots, N$. And the solution for Equation 44.8 is

$$P(t + s) = P(t) \cdot Z(0) \cdot Z(1)...Z(N) \cdot \exp$$
$$\{(\alpha - \beta^2/2)s + \beta\sqrt{(s)}W\} \qquad (44.9)$$

Divide Equation 44.9 by $P(t)$ and take natural logarithms, then

$$\ln[P(t + s)/P(t) = (\alpha - \beta^2/2)s$$
$$+ \beta\sqrt{(s)}W+] \sum_{i=1}^{N} \log Z(i). \qquad (44.10)$$

According to the Equation 44.10, we can see the third term of Equation 44.10 is the jump process. If $N = 0$ then ln $[P(t + s)/P(s)]$ is normally distributed with mean $(\alpha - \beta^2/2)s$ and variance $\beta^2 s$. If the ln $Z(i)$ are assumed to be identically distributed with mean μ and finite variance σ^2, a general form of joint density for ln $Z(i)$ can be represented by:

$$f(\ln Z(1), \cdots, \ln Z(N)) = \int_{-\infty}^{\infty} f(\ln Z(1), \cdots,$$
$$\ln Z(N), W)dW,$$

with:

$$E[\ln Z(i)] = \mu, \text{ for } i= 1, \cdots, N,$$
$$\text{Var}[\ln Z(i)] =\sigma^2, \text{ for } i= 1, \cdots, N,$$
$$\text{Cov}[\ln Z(i), \ln Z(i - j)] =\rho_j\sigma^2, \text{ for } j\geq 0.$$

where ρ_j is the correlation between $\ln Z(i)$ and ln $Z(i - j)$. The index i represents the jump number while the index j denotes the number of lags between jumps. The startling feature of this general joint density is the autocorrelation among jumps. Hence, some major conclusions are drawn from the data analysis: (1) A geometric Brownian motion process or a subordinated process does not alone describe the

sample data very well. (2) Stock returns seem to follow an autoregressive jump process based on the sample means and variances of transaction returns. (3) In contrast to the previous empirical work which is not sufficiently detailed to determine the probability law for transaction returns, the probability density for the time intervals between jumps is gamma.

44.9 Jump Diffusion Models with Conditional Heteroscedasticity

44.9.1 Conditional Jump Dynamics

The basic jump model has been extended in a number of directions. A tractable alternative is to combine jumps with an ARCH/GARCH model in discrete time. It seems likely that the jump probability will change over time. Ho et al. (1996) formulate a continuous-time asset pricing model based on the work of Chamnerlain (1988), but include jumps. Their work strongly suggested that both jump components and heteroscedastic Brownian motions are needed to model the asset returns. As the jump components are omitted, the estimated rate of convergence of volatility to its unconditional mean is significantly biased. Moreover, Chan and Maheu (2002) developed a new conditional jump model to study jump dynamics in stock market returns. They present a discrete-time jump model with time varying conditional jump intensity and jump size distribution. Besides, they combine the jump specification with a GARCH parameterization of volatility. Consider the following jump model for stock returns:

$$R_t = \mu + \sum_{i=1}^{t} \phi R_{t-i} + \sqrt{h_t}z_t + \sum_{k=1}^{n_t} Y_{t,k},$$
$$z_t \sim NID(0, 1), \quad Y_{t,k} \sim N(\theta_t, \delta^2). \qquad (44.11)$$

Define the information set at time t to be the history of returns, $\Phi_t = \{R_t, \cdots, R_1\}$ The conditional jump size $Y_{t,k}$, given Φ_{t-1}, is presumed to be independent and normally distributed with mean θ_t and variance δ^2. Denote n_t as the discrete counting process governing the number of jumps that arrive between $t - 1$ and t, which is distributed as a Poisson random variable with the parameter $\lambda_t > 0$ and density

$$P(n_t = j|\Phi_{t-1}) = \frac{\exp(-\lambda_t)\lambda_t^j}{j!}, \quad j = 0, 1, 2, \cdots. \qquad (44.12)$$

The mean and variance for the Poisson random variable are both λ_t, which is often called the jump intensity.

The jump intensity is allowed time-varying. h_t is measurable with respect to the information set Φ_{t-1} and follows a GARCH(p,q) process,

$$h_t = w + \sum_{i=1}^{q} \alpha_i \varepsilon_{t-i}^2 + \sum_{i=1}^{p} \beta_i h_{t-i},$$

where $\varepsilon_t = R_t - \mu - \sum_{i=1}^{p} \phi_i R_{t-i}$. ε_t contains the expected jump component and it affects future volatility through the GARCH variance factor. Moreover, based on a parsimonious ARMA structure, let λ_t be endogenous. Denote the following ARJI(r,s) model:

$$\lambda_t = \lambda_0 + \sum_{i=1}^{r} \rho_i \lambda_{t-i} + \sum_{i=1}^{s} \gamma_i \xi_{t-i}$$

$\lambda_t = E[n_t|\Phi_{t-1}]$ is the conditional expectation of the counting process. ξ_{t-i} represents the innovation to λ_{t-i}. The shock jump intensity residual is

$$\xi_{t-i} = E[n_{t-i}|\Phi_{t-i}] - \lambda_{t-i}$$
$$= \sum_{j=0}^{\infty} j P(n_{t-i} = j|\phi_{t-i}) - \lambda_{t-i}. \qquad (44.13)$$

The first term of Equation 44.13 is average number of jumps at time $t - i$ based on time $t - i$ information. Therefore, ξ_{i-i} represents the unpredictable component about the conditional mean of the counting process n_{t-i}. Moreover, having observed R_t, let $f(R_t|n_t = j, \Phi_{t-1})$ denote the conditional density of returns given that j jumps occur and the information set Φ_{t-1}, we can get the expost probability of the occurrence of j jumps at time t, with the filter defined as

$$P(n_t = j|\Phi_t) = \frac{f(R_t|n_t = j, \Phi_{t-1}) P(n_t = j|\Phi_{t-1})}{P(R_t|\Phi_{t-1})},$$
$$j = 0, 1, 2, \cdots, \qquad (44.14)$$

where, the definition of $P(n_t = j|\Phi_{t-1})$ is the same as Equation 44.12. The filter in Equation 44.14 is an important component of their model of time varying jump dynamics. Thus, the conditional density of return is

$$P(R_t|\Phi_{t-1}) = \sum_{j=0}^{\infty} f(R_t|n_t = j, \Phi_{t-1}) P(n_t = j|\Phi_{t-1}). \qquad (44.15)$$

Equation 44.15 shows that this model is nothing more than a discrete mixture of distribution where the mixing is driven by a time varying Poisson distribution. Therefore, from the assumption of Equation 44.11, the distribution of returns conditional on the most recent information set and j jumps is normally distributed as

$$f(R_t|n_t = j, \Phi_{t-1}) = \frac{1}{\sqrt{2\pi(h_t + j\delta_t^2)}} \times \exp$$
$$\left(-\frac{\left(R_t - \mu - \sum_{i=1}^{l} \phi_i R_{t-i} - \theta_t j\right)^2}{2(h_t + j\delta_t^2)} \right).$$

Equation 44.14 includes an infinite sum over the possible number of jumps n_t. However, practically, they consider truncating the maximum number of jumps to a large value τ, and then they set the probability of τ or more jumps to 0. Hence, the first way to choose τ is to check Equation 44.12 to be equal to 0 for $j \geq \tau$. The second check on the choice of τ is to investigate $\tau > \tau$ to make sure that the parameter estimate does not change.

The ARJI model illustrates that conditional jump intensity is time varying. Suppose that we observe $\xi_\tau > 0$ for several periods. This suggests that the jump intensity is temporarily trending away from its unconditional mean. On the other hand, this model effectively captures systematic changes in jump risk in the market. In addition, they find significant time variation in the conditional jump intensity and the jump size distribution in their application for daily stock market returns. Accordingly, the ARJI model can capture systematic changes, and also forecast increases (decreases) in jump risk into the future.

44.9.2 ARCH/GARCH Jump Diffusion Model

As described in Drost et al. (1998) there exists a major drawback of Merton's (1976) model which implies that returns are independent and identically distributed at all frequencies that conflict with the overwhelming evidence of conditional heteroscedasticity in returns at high frequencies, because all deviations from log normality of observed stock returns at any frequency can be attributed to the jumps in his model. Thus, several papers consider the size of jumps within the models that also involve the conditional heteroscedasticity.

Jorion (1988) considered a tractable specification combining both ARCH and jump processes for foreign exchange market:

$$\ln(P_t/P_{t-1})|t - 1 = \mu + \sqrt{(b_t)}z + \sum_{i=1}^{n_t} \ln(Y_t),$$
$$b_t = E_{t-1}(\sigma_t^2) = \alpha_0 + \alpha_1(x_{t-1} - \mu)^2$$

in which α_1 is the autoregressive parameter inducing heteroskedasticity and the distribution of x_t is conditional on information at $t-1$ and define x_t as the logarithm of price relative $\ln(Pt/P_{t-1})$. A jump size Y is assumed independently log normally distributed, $\ln Y \sim N(\theta, \delta^2)$, n_t is the actual number of jumps during the interval. z is a standard normal deviate. Consequently, his results reveal that exchange rate exhibit systematic discontinuities even after allowing for conditional heteroskedasticity in the diffusion process. In brief, in his work, the maximum likelihood estimation of a mixed-jump diffusion process indicates that ignoring the jump component in exchange rates can lead to serious mispricing errors for currency options. The same findings also can be found in Nieuwland et al. (1991) who allow for the model with conditional heteroscedasticity and jumps in exchange rate market. Also, an application of a GARCH jump mixture model has been given by Vlaar and Palm (1993). They point out that the GARCH specification cum normal innovation cannot fully explain the leptokurtic behavior for high-frequency financial data. Both the GARCH specification and the jump process can explain the leptokurtic behavior. Hence, they permit autocorrelation in the mean higher-order GARCH effect and Bernoulli jumps.

A weak GARCH model can be defined as a symmetric discrete-time process $\{y_{(h)t}, t\ h\text{Å}\}$ with finite fourth moment and with parameter $\zeta_h = (\phi_h, \alpha_h, \beta_h, \kappa_h)$, if there exists a covariance-stationary process $\{\sigma_{(h)t, th\alpha}\}$ with

$$\sigma^2_{(h)t+h} = \phi_h + \alpha_h y^2_{(h)t} + \beta_h \sigma^2_{(h)t}, \quad t \in h\text{A}$$

and we denote $\kappa_h = \dfrac{E y^4_{(h)t}}{\left(E y^2_{(h)t}\right)^2}$ as the kurtosis of the process.

Roughly speaking, the class of continuous-time GARCH models can be divided into two groups. One is the GARCH diffusion in which the sample paths are smooth and the other, where the sample paths are erratic. Drost and Werker (1996) developed several properties of discrete-time data that are generated by underlying continuous-time processes that accommodate both conditional heteroscedasticity and jumps. Their model is as follows. Let $\{Y_t, t \geq 0\}$ be the GARCH jump diffusion with parameter vector $\zeta_h = (\phi_h, \alpha_h, \beta_h, \kappa_h)$ and suppose α_{h0} for some $h_0 > 0$. Then, there exists $\omega\ (0, \infty)$, $\theta\ (0, \infty)$, $\phi\ (0, \infty)$, $\upsilon\ (0, \infty)$ and c_h and κ_h are given by

$$c_h = \frac{4\{\exp(-h\theta) - 1 + h\theta\} + 2h\theta\left\{1 + \frac{\upsilon + 2h\theta}{\upsilon\phi(2+\phi)}\right\}}{1 - \exp(-2h\theta)},$$

$$\kappa_h = 3 + \frac{\upsilon}{h\theta} + 3\upsilon\phi(2+\phi)\frac{\exp(-h\theta) - 1 + h\theta}{(h\theta)^2},$$

such that ζ_h (with $|\beta_h| < 1$) is determined by

$$\Psi_h = h\omega\{1 - \exp(-h\theta)\},$$

$$\alpha_h = \exp(-h\theta) - \beta_h, \quad \frac{\beta_h}{1 + \beta^2_h} = \frac{c_h \exp(-h\theta) - 1}{c_h\{1 + \exp(-2h\theta)\} - 2},$$

where θ is the time unit and scale is denoted by ω. ϕ and υ are slope parameters and ϕ will denote slopes in the $(\alpha_h \cdot \beta_h)$ plane, while v determines the slope of the kurtosis at very high frequencies. Drost et al. (1998) employed the results of Drost and Werker (1996), which stated that for GARCH diffusion at an arbitrary frequency h, the five discrete-time GARCH parameters can be written in terms of only four continuous-time parameters, i.e. an over identifying restriction in GARCH diffusion, for proposing a test for the presence of jumps with conditional heteroscedasticity, which is based on the following Theorem 1.

Theorem 1 *Let $\{Y_t: t \geq 0\}$ be a continuous-time GARCH diffusion. Then $\theta > 0$ and $\lambda \in (0, 1)$ is defined by*

$$\theta = -\ln(\alpha + \beta)$$

$$\lambda = 2\ln^2(\alpha + \beta)\left\{\frac{\left\{1 - (\alpha + \beta)^2\right\}(1 - \beta)^2}{\alpha - \alpha\beta(\alpha + \beta)}\right.$$
$$\left. + 6\ln(\alpha + \beta) + 2\ln^2(\alpha + \beta) + 4(1 - \alpha - \beta)\right\}$$

$$\kappa = 3 + 6\frac{\lambda}{1 - \lambda}\frac{\exp(-\theta) - 1 + \theta}{\theta^2}$$

Thus, we set up the null and alternative hypotheses:

H_0: $\{Y_t: t \geq 0\}$ is a GARCH diffusion model and H_1: $\{Y_t: t \geq 0\}$ is a GARCH jump diffusion model.

From Theorem 1, by simple calculation, we yield the relation between functions K and κ:

$$K(\alpha, \beta, \kappa) = \kappa - \kappa(\alpha, \beta) = 0$$

for GARCH diffusion. Furthermore, in Drost and Werker (1996), they showed that $K(\alpha, \beta, \kappa)$ will be strictly larger than 0 for any GARCH jump diffusion model. As a result, H_0 is equivalent to $K(\alpha, \beta, \kappa) = 0$ and H_1 is equivalent to $K(\alpha, \beta, \kappa) > 0$. In other words, this test can be viewed as the kurtosis test for presence of jumps with conditional heteroscedasticity. As well, it indicates the presence of jumps in dollar exchange rate.

44.10 Other Jump Diffusion Models

As shown in Chacko and Viceira (2003), the jump diffusion process for stock price dynamics with asymmetric upward and downward jumps is

$$\frac{\mathrm{d}S_t}{S_t} = \mu \mathrm{d}t + \sigma \mathrm{d}Z + [\exp(J_u) - 1]\mathrm{d}N_u(\lambda_u)$$
$$+ [\exp(-J_d) - 1]\mathrm{d}N_d(\lambda_d).$$

$[\exp(J_u) - 1]\mathrm{d}N_u(\lambda_u)$ and $[\exp(-J_d) - 1]\mathrm{d}N_d(\lambda_d)$ represent a positive jump and a downward jump, respectively. J_u, $J_d > 0$ are stochastic jump magnitudes, which implies that the stock prices are non-negative, λ_d, $\lambda_u > 0$ are constant, and also determine jump frequencies. Furthermore, the densities of jump magnitudes,

$$f(J_u) = \frac{1}{\eta_u} \exp\left(-\frac{J_u}{\eta_u}\right) \quad \text{and}$$

and

$$f(J_d) = \frac{1}{\eta_d} \exp\left(-\frac{J_d}{\eta_d}\right)$$

are drawn from exponential distributions. Note that μ and $\cdot\sigma$ are constants.

To estimate this process, they provide a simple, consistent procedure – spectral GMM by deriving the conditional characteristic function of that process.

Networks, Nodes, and Priority Rules

Daniel G. Weaver

Abstract

In the United States, the same stock can be traded at different locations. In the case of listed stocks, each location is a node in national network called the Intermarket Trading System (ITS). Unlisted stocks also trade at different nodes on the National Association of Securities Dealers Automated Quotation (NASDAQ) network. Each node of these two networks may have rules for breaking queuing ties among competing orders. Orders may be routed on the networks according to official rules (as with ITS) or order preferencing arrangements (both networks). This paper examines the impact of priority rules on individual markets and networks. The development of the ITS and NASDAQ networks as well as the relevant literature is discussed. I conclude that network priority rules improve market quality if they result in consolidated markets.

Assume that an investor wants to sell 100 shares of stock and a number of people are willing to buy it. Who should get to buy the 100 shares? If asked, the average person would say, the trader offering the highest price. What if there is more than one trader offering the same price? The average person would answer the trader who quoted the price first. However, many times, the trader quoting the best price first does not get to trade. An understanding of the determinants of trade sequencing (called priority rules) will assist investors in designing trading strategies. This paper will review the different types of priority rules as well as the literature on the subject.

Related to priority rules is the concept of order routing. The average person conceives of a market for stock as a single entity. While it is true that Microsoft is a The National Association of Securities Dealers Automated Quotation (NASDAQ)-listed stock, the NASDAQ system is only one node in a network, any one of which could execute a trade for Microsoft. Similarly, there are more than a handful of markets in the United States that trade New York Stock Exchange (NYSE)-listed GE. The markets for both Microsoft and GE can be thought of as networks with multiple nodes. Each node may or may not have similar priority rules to the other nodes in the network.

In addition, networks may have priority rules that govern the routing of orders within the network (as does the network for NYSE stocks) or may not have network-wide priority rules (this is the case on NASDAQ). In fact, recently, the U.S. Securities and Exchange Commission (SEC) and derivatively Congress have begun addressing the issue of whether networks should have priority rules. The SEC has proposed imposing network-wide priority rules on NASDAQ, while some market forces have tried to convince the Congress that not only should NASDAQ not have network-wide priority rules, they have also lobbied to eliminate NYSE-listed network priority rules.

From the brief discussion just presented, it is clear that a submitted order faces a maze of routing and priority rules.

D.G. Weaver (✉)
Rutgers University, New Brunswick, NJ, USA
e-mail: daniel_weaver@business.rutgers.edu

Therefore, this paper will address these issues in hopes of shedding light on the relevant factors in designing an optimal network with regard to network routing and node priority rules.

In the following section, I shall discuss different types of priority rules in use in markets today as well as the literature on the subject. In Section 45.2, I will present a history of how the networks for NYSE-listed and NASDAQ stocks developed, which includes routing rules. In the Section 45.3, I will discuss the current political and regulatory environment concerning stock networks. I will also discuss whether networks benefit from priority rules. In the final section, I conclude.

45.1 Priority Rules

Markets and network nodes use a variety of priority rules to match buyers with sellers.[1] Typically, price takes the highest priority: The buyer willing to pay the most is entitled to trade with the next seller willing to sell at the buyer's bid price and vice versa. However, if there is a tie in which more than one buyer is willing to buy at a different price, markets use a variety of different rules to decide who gets to purchase from the next seller. Here is a sample of the different secondary rules[2]:

Time priority represents a first-come, first-served model. The first order submitted at a given price is the first one to be filled. The American Stock Exchange, Paris Bourse, Tokyo Stock Exchange, and Toronto Stock Exchange Computer-Assisted Trading System (CATS) prior to 1996 used some variation of this method. However, it is by no means clear that time priority is the most desirable secondary priority rule for a market. Indeed, few financial markets use pure time priority.[3]

Class priority gives priority to certain classes of traders over others. For example, on the Toronto Stock Exchange the Registered Trader has a higher priority than orders on the book in that he or she can participate in certain incoming trades up to half the minimum guaranteed fill. On the NYSE, however, the specialist cannot trade ahead of the limit order book. In a dealer market such as the old NASDAQ system (prior to the new order handling rules), dealers could take priority over customer orders – even if customer orders at a better price – because the customers have no means of bypassing the intermediaries. We will discuss dealer priority in more depth later in the paper.

Random priority randomly assigns an order among the traders willing to trade at a given price. Each floor trader willing to trade at a given price has an equal probability of filling the next order. This is effectively what happens in the "open outcry" method found in floor-based futures trading pits such as the Chicago Board of Trade.

Sharing or *pro rata priority* is also a common practice on many trading floors including the Stock Exchange of Hong Kong and the old Toronto Stock Exchange floor-based system. A sharing priority rule could allocate equal shares to each order on the book. Alternatively, the allocation could be proportional to the total size of a member's orders on the book (pro rata sharing.) However, even if a trading floor has a time priority rule, it may be virtually impossible to determine who was first. For example, a large order may arrive at a trading venue where there are several traders willing to fill the order. Therefore, a large order may be de facto shared among many traders.

Size priority grants priority to orders based on their size. Priority could be granted to the largest order, which has the advantage of giving traders an incentive to place larger orders.[4] Alternatively, priority could be granted to the order that matches the incoming order in size. This minimizes the number of trade tickets to be processed. A variation of this secondary priority rule is used on the New York Stock Exchange.

Exposure priority grants priority to orders that are revealed to other market makers and reduces the priority for those traders who want to hide their orders. On the old CATS system and the Paris Bourse, traders can hide a portion of their orders from exposure on the electronic systems.

These different secondary priority rules have strong implications for the ways that investors compete to obtain an order fill. In a pure time priority market, an investor who is the first to put in a bid at a higher price is first in line to fill the next market sell order. With random or sharing priority there is much less incentive to pay up by bidding higher. This is because there is a positive probability that a trader can obtain a fill, within the same time to execution as bidding higher, by merely matching existing quotes.

Therefore, it can be seen that priority rules can have an impact on market quality. For example, in systems with time as the secondary priority rule, traders have incentives to improve on the price since merely matching a current best price puts them at the back of the queue. This could lead to narrower spreads. Similarly, in systems where public orders take priority over market maker or specialist orders, there will be more public orders submitted. This can lead to more liquidity being supplied.

45.2 Literature on Priority Rules

Cohen et al. (1985) find support for the notion that time priority leads to more price competition and, hence, narrower spreads. They use a simulated queuing model to show that systems that do not enforce time priority have wider spreads relative to those that enforce time priority.

Angel and Weaver (1998) and Panchapagesan (1998) compare market quality and investor behavior differences between systems that use time priority as their secondary rule with systems that use pro rata sharing. In particular,

Angel and Weaver examine the 29 July 1996 switch from time to sharing priority for stocks in the Toronto Stock Exchange's (TSX) CATS. Panchapagesan also examines the TSX but compares a matched sample of CATS stocks with stocks traded on the TSX floor. During Panchapagesan's sample period the TSX floor used sharing priority rules while CATS used time priority.

Both studies find that a sharing priority rule results in less price competition compared with a time priority rule. They also find that a sharing priority rule results in more gaming behavior by investors in an attempt to get their orders filled. For example, a sharing priority rule encourages investors to submit larger orders and then cancel them when their desired volume is filled. Panchapagesan (1998) additionally concludes that the lack of price competition in sharing priority rule systems results in wider bid ask spreads than under time priority.

Cordella and Foucault (1999) develop a theoretical model of dealer competition and also conclude that spreads will be wider under a random allocation rule than under a price/time priority system. The intuition is that under a random allocation rule dealers can always match other dealers' quotes without losing priority.

Harris (1994) addresses the relationship between priority rules, tick size, and depth.[5] Harris points out that large ticks and time priority protect traders that place limit orders. If a trader wants to trade ahead of another in a time priority rule system, he or she must improve on the price. A large tick makes obtaining precedence costly.[6] Harris then argues that time priority encourages traders to quote more size, which leads to greater quoted depth.

Two points are evident from the above discussion. First, traders will change their behavior as rules change. Second, the behavior of these traders impacts market quality and hence the terms of trade for unsophisticated traders.

45.3 Networks

Thus far, the discussion of priority rules has assumed that there is a single market for stocks. That is markets are consolidated. What if there are multiple markets? In this section, I will discuss networks of markets and how priority rules may apply to them. I will also consider the development of two major network structures: one for listed stocks such as those on the NYSE and another for over-the-counter (OTC) stock.

45.3.1 The Network for Listed Stocks

During the first half of the twentieth century, the role of regional stock exchanges changed and their number decreased dramatically. When regional stock exchanges like the Boston Stock Exchange were first established, there was poor telecommunications in the United States and travel was expensive. As a result, it was very difficult for investors away from a company's headquarters to find out anything about the company. Therefore, regional stock exchanges were established as a place to trade local companies. As telecommunications improved and travel became less expensive, it became easier to find out about companies located in distant geographic locations. As companies grew, they switched listed on the American or New York Stock Exchanges where they could obtain the prestige of a national listing.

So, the regional exchanges experienced a dramatic drop in listings. Perhaps to provide another source of revenue, local traders began trading NYSE-listed stocks. Multiple trading venues for the same NYSE-listed stock led to frequent differences in prices across markets. Stories are abound of traders paying for open phone lines between the NYSE and one of the regional stock exchanges so that they could capitalize on the discrepancies. Over time, Congress observed that prices for NYSE-and Amex-listed stocks varied widely across the exchanges that traded them. This led to the passage of the Securities Act Amendments of 1975 in which Congress ordered the SEC to create a National Market System (NMS) that, in part, would allow investors to execute trades on markets that displayed the best price.

After deliberation, on 26 January 1978, the SEC issued the Exchange Act Release No. 14416 that required markets to create a network that would "permit orders for the purchase and sale of multiple-traded securities to be sent directly from any qualified market to another such market promptly and efficiently."[7] Two months later, the American, Boston, NYSE, Pacific, and Philadelphia Stock Exchanges submitted a "Plan for the Purpose of Creating and Operating an Intermarket Communications Linkage." This became known as the Intermarket Trading System (ITS).

The ITS allowed exchanges to route orders to each other. It was in effect an e-mail system in which the specialist on an exchange could ask a specialist on another exchange if they would be willing to trade at their quoted price.[8] A few months later, the SEC also created the Consolidated Quote System (CQS), which collected the best quoted prices to sell (called the offer) and buy (called the bid) securities. The CQS then constructed the best bid and offer (BBO) and disseminated it to the exchanges and data vendors who disseminated it to the public.

Although the ITS established a network and a method for routing orders, there initially was no rule indicating under what circumstances participants were to route orders to another exchange. Nor was the OTC market a part of the linkage. The NASDAQ traded many NYSE and Amex stocks. After the passage of the Securities Act Amendments

of 1975, they began work on a Computerized Automated Execution System (CAES) to interface with ITS. Finally, on 28 April 1981, the SEC issued an order requiring that CAES become a part of ITS.

That same month, the SEC issued Securities Exchange Act Release No. 17703 that prohibited ITS/CAES participants from executing orders at prices inferior to those displayed on another network node. This requirement became known as the trade through rule and established a network-wide priority system for investor orders. The rule requires an exchange to either match a better price or route the order to the exchange displaying the better price.

The effect of the trade through rule was and is to establish price as the first priority rule across the ITS network. In turn, each regional exchange (a node) has its own priority rules.[9] So, an order reaching any node of the ITS network was first subject to a network-wide price priority rule and then the node's priority rules.

45.3.2 The Network for OTC Stocks

In the previous section, I discussed how a network for exchange-listed stocks developed. While exchanges list many stocks in the United States, the majority of stock issued are traded OTC, so-called because you went to your broker's office and purchased them at the front counter. In the early part of the twentieth century, there was no organized way to buy and sell OTC stocks and so many times investors or brokers resorted to newspaper ads to accomplish the task.

In 1913, the National Quotation Bureau was formed by two businessmen who collected and published daily quotations from dealers of securities in five different cities. Their publication became known as the Pink Sheets because of the color of the paper they were printed on. For each stock the Pink Sheets listed the brokers trading the stock and representative quotes. The quotes were old, but at least brokers had a list of other brokers who were interested in trading a particular stock issue. Brokers would contact those listed in the Pink Sheets to get current quotes. Because of the large number of listed brokers for some stocks and the amount of time necessary to call each one, a rule was developed over time that required brokers to contact at least three (but not all) of the brokers listed on the Pink Sheets in order to try and find the best price for customers. Due to the lack of continuous investor interest in OTC stocks, the market developed as a dealer market who would act as intermediaries between investors – buying and selling stocks to earn a profit.

The vast majority of stock issues (but not stock volume) were traded this way for almost 60 years. As companies grew, they typically listed on an exchange. Over time, though telecommunications improved and the Pink Sheets expanded

their coverage to nationwide. This increased the number of dealers making markets in a particular stock and made the goal of finding investors the best price more difficult. So, in 1971, the National Association of Securities Dealers (NASD) created an automated quotation system with the acronym NASDAQ for trading the more active OTC issues. The system allowed dealer members to input contemporaneous quotations for stocks they made a market in. NASDAQ was similar in its aggregating function to the CQS for listed stocks. Brokers still needed to telephone dealers to trade. And NASDAQ was a dealer market. While the exchanges established prices based on a combination of public limit orders and specialist quotes, NASDAQ displayed *dealer* quotes.[10, 11]

Initially, NASDAQ dealers could ignore customer limit orders. Customers learned that limit orders were not executed and did not submit them. In 1994, an investor sued his broker and as a result NASDAQ established a rule which came be known as Manning I. The rule prevented NASDAQ dealers from trading through *their* customer limit orders at better prices – much like ITS trade through rules do.[12] However, after the passage of Manning I, NASDAQ dealers could still trade at the same price as customer limit orders they held, i.e. there was no public order priority rule. This was in contrast to the exchanges that had public priority rules. NASDAQ customers were still reluctant to submit limit orders. A year later, another rule, Manning II, gave public limit orders priority, but only within a dealer firm. In other words, a customer submitting a limit order to Dealer X could still see trades occurring at other dealers at the same price as the customer's limit order. Thus, Manning II still discouraged public limit order submission and as a result they were not a major supplier of liquidity on the NASDAQ market.

So it can be seen that although NASDAQ was a network of dealers, it had no market-wide priority rules as did the exchanges. In addition, proprietary trading systems were established that allowed NASDAQ dealers to trade between themselves at prices that were better than the best quotes on NASDAQ. Like it had for exchanges, Congress and the SEC acted and established a method for investors to access the best quoted prices. However, the landscape for NASDAQ stocks in the 1990s was different than that for exchange listed stocks in 1975. While a number of exchanges were trading the same stocks in 1975, there were really only two players for NASDAQ stocks by the mid-1990s. Other than NASDAQ itself, where dealers traded with the public, the only other place NASDAQ stocks were traded was on a proprietary system called Instinet.[13]

Most, if not all, NASDAQ dealers also were already connected to Instinet; so, rather than create a new network, the SEC required that Instinet quotes be made part of the BBO for NASDAQ stocks. The Order Handling Rules (OHR), enacted in early 1997, also required NASDAQ dealers to expose customer limit orders to the public by

including them in their quotes. Rather than specifically including Instinet into the calculation of the BBO, the SEC generalized the rule to include *any* system for displaying limit orders for NASDAQ stocks. These systems were referred to as Electronic Communications Networks (ECNs) and a number of new systems were established in anticipation of the OHR or shortly after its passage.

These ECNs unleashed the potential of public limit orders. After the OHR, spreads dropped dramatically with most of the drop attributed to public limit orders competing with dealer quotes.[14] ECNs grew in market share from around 20% in 1997 to 80% today. The OHR created a much larger network of systems than ITS ever faced. At the time of the OHR, the SEC did not require a trade through rule for the NASDAQ/ECNs network as it did for ITS.

45.3.3 Do Networks Need Priority Rules?

During 2004 the SEC proposed Regulation NMS. Part of the rule proposes to extend the ITS trade through rule to NASDAQ. On 10 February 2004, Congressman Richard Baker sent SEC Chairman William Donaldson a letter calling the ITS trade through rule "antiquated" and calling for its complete repeal. Congressman Baker suggested that execution speed was just as important as price and that investors should be allowed to choose whether they wanted price or speed to be the primary routing rule.

There is support for Congressman Baker's position in the academic literature. For example Hatch et al. (2001) compare trade executions for NYSE-listed stocks between different nodes on the ITS/CAES network. They find that investors receive better prices on the NYSE, but the regional exchanges offer more speed of execution and larger execution sizes. In addition, Battalio et al. (2002) examined limit orders execution. They find that at-the-inside limit orders do better on regional exchanges in terms of speed of execution (perhaps due to shorter queues) than on NYSE, but quote improving limit orders do better on the NYSE where they execute faster and more profitably.

Congressman Baker's letter then raises the question: Do networks need priority rules? On its face, it would seem obvious that investors should be allowed to send orders wherever they choose. However, overall market quality must be balanced against the needs of individual traders. If the needs of the individual do not cause harm to the overall population then the individual should be allowed to route orders as they wish. If however, the overall population of traders is harmed by the choices of the individual then the needs of the majority out-weigh the individual's needs.

A similar argument is used to justify nonsmoking areas. While an individual aware of smoking's risks has the right to smoke, the impact of second-hand smoke on nonsmokers is such that nonsmokers will be harmed if smokers exercise their right to smoke around them. Therefore, various laws have been enacted to protect non-smokers from the harmful affects of second-hand smoke. The greater good comes down on the side of providing nonsmokers with a smoke-free environment.

Following the smoking analogy, the ability of traders to choose their priority rules should be weighed against overall market quality. For this purpose, the literature on consolidation and fragmentation becomes useful. In a consolidated market, order flow is concentrated in a single location. In a fragmented market, order flow is split up between multiple locations. The number of choices between consolidated and fragmented is a continuum not a bifurcation.

A number of papers have been written on the subject of fragmented versus consolidated markets. They generally conclude that consolidated markets offer better market quality than fragmented markets. For example, Madhavan (2000) developed a theoretical model that shows that fragmented markets have higher volatility than consolidated markets. Wei and Bennett (2003) find empirical support for Madhavan's conjecture. In particular, they find that stocks that switch from the fragmented NASDAQ to the comparatively consolidated NYSE, experience a reduction in spread and volatility.[15] Barclay et al. (2003) examined stock price and volume around quarterly expirations of the S&P 500 futures contract (so called witching days). They found that NYSE prices are more efficient than NASDAQ prices. They attributed the superior performance of the NYSE to the larger degree of order flow consolidation found there relative to NASDAQ.

Battalio et al. (1998) examined Merrill Lynch's decision to route all orders for NYSE-listed stocks to the NYSE rather than to a regional exchange where they could effectively internalize the order flow. They found that, consistent with other studies, the NYSE routing decision resulted in investors obtaining better prices and spreads narrowing.

Murphy and Weaver (2003) examined the TSX rule that require brokers receiving market orders of 5,000 shares or less, to either improve on price or send the order to the TSX for execution against limit orders. Following the adoption of the rule, the affected stocks experienced an immediate increase in depth and reduction in spread.[16] In addition to the TSX, many other exchanges around the world have so-called concentration rules.

Therefore, the extant literature suggests that overall market quality is higher in consolidated versus fragmented markets. The NYSE market share of its listed stocks is around 80% and they display the best price over 90% of the time. Therefore the market for NYSE stocks can be considered relatively consolidated. Although never empirically tested, there appears to then be a link between percentage of the time a market displays the best price and its market share. So the ITS network price priority rule may be the mechanism that causes the consolidation of NYSE
stocks. If orders are routed away from the NYSE to another
exchange or market maker then the market for NYSE stocks
will become more fragmented. The academic literature
suggests that an increase in fragmentation will result in
wider spreads and higher volatility. It has been shown,
time and time again, that investors factor execution costs
into their required cost of supplying funds to firms.[17] There-
fore, higher execution costs will translate into higher costs of
capital for firms and stock prices will fall.

Figure 45.1 illustrates the relationship between execution
costs and stock prices.[18] On 11 April 1990, the TSX enacted
rules that resulted in effective execution costs rising by about
0.25% points. Within a week, prices declined by over 6%.

It can, therefore, be concluded that a network priority rule
based on price results in improved market quality. Although a
direct empirical link can only be proven by examining what
happens if the network price priority rule is removed, logical
inferences can be drawn from examining the behavior of
those traders that supply liquidity to the market. The follow-
ing section discusses the behavior of limit order traders who
are the major supplier of liquidity on the NYSE.[19]

45.3.4 Liquidity Supplied by Limit Order Traders

There is an old adage that "liquidity begets liquidity." In other
words, limit order traders will submit limit orders where mar-
ket orders exist. It is similar to the fact that the more traffic
exists on a highway, the more gas stations will exist. If the
traffic goes away so will the gas stations. Similarly, if market
orders get routed away from the venue with the best price, limit
orders will leave that venue as well. There will be less price
competition and, as a result, spreads will widen.

Limit orders are shock absorbers for liquidity events.
Without limit orders to absorb trades from liquidity
demanders, large orders will increasingly push prices away
from current prices.[20] While it may be argued that price
impact is a fact of life for institutions, small traders who
submit order in the same direction, but just behind the large
order may suffer financial loss. The small order will execute

at an inferior price before sufficient liquidity can be sent to
the market by traders. It can then be seen that thin markets
are more susceptible to liquidity event volatility than deeper
markets.[21] Thus, markets with more depth are desirable.

The TSX market concentration rules best illustrate the
above points. Prior to the adoption of the rule, it was common
practice for member firms to execute market orders and
marketable limit orders from the member's own inventory
(called internalization). Limit order traders realized that even
if they had the best quoted price, many orders would never
reach them and they would not get timely executions.[22] The
TSX adoption of its concentration rules caused more market
and marketable limit orders to be submitted to the exchange
where they could execute against limit orders. The increase
in order flow to the exchange caused more limit order traders
to compete for the order flow. This, in turn, resulted in
narrower spreads and more quoted depth.

This section of the paper suggests that networks without
priority rules discourage limit order submission which results
in higher effective execution costs for the average investor. A
few large players may benefit from the absence of a network
priority rule, but it will be at the expense of the majority of
long-term investors. Therefore, it can be seen that overall
market quality benefits from network priority rules.

45.3.5 A Final Note on the Need for Speed

In the current drive to eliminate priority rules for the ITS
network, the most common reason cited is a desire to get a
trade done quickly – perhaps in a second or less. Is this
advantageous? Perhaps examining a graph of a random
stock on a random day would help. Figure 45.2 is the
graph representing all trades in Juniper Inc. (JNPR) for 3
February 2003 from 10:00 AM until 10:01:30 AM.

It can be seen that getting an order filled at 10:00:51
compared to 10:00:52 may save you $0.02 on that trade.
However, if we examine JNPR over the entire day it can be
seen that prices fluctuated by $0.20 over the day, a factor of
10. So, price changes over small-time increments are much
smaller than over longer increments (Figure 45.3). In that
case, what type of trader benefits from small price changes
Fig. 45.2 JNPR 3 February 2003 10:00 to 10:01:30 AM
Fig. 45.3 Juniper corporation 3 February 2003

and, hence, needs speed? The answer is arbitrageurs and hedge funds. As mentioned earlier, if we allow orders to be routed for other than best price, then limit order traders will reduce the amount of liquidity they supply, increasing execution costs. It can then be seen that this "need for speed" benefits the few at the expense of the many

Conclusion

In this paper, I have considered priority rules as they apply to individual markets (nodes) and networks. The literature on priority rules suggests that the adoption of some priority rules can improve market quality within a node. After a discussion of the development of the ITS and NASDAQ networks, I consider whether network priority rules matter. Since a network's priority rules (or routing rules) can result in a concentration of orders, I discuss the literature on consolidated versus fragmented markets. I conclude that network priority rules improve the market quality if they result in consolidated markets. This further suggests that the current price priority rule on ITS should, therefore, be retained and extended to the NASDAQ network as proposed by the SEC.

Notes

1. See Domowitz (1993) for taxonomy of many of the different rules found in different markets.
2. The following list is taken from an unpublished paper I co-authored with James Angel entitled "Priority Rules."
3. For example, on the old TSE CATS system, time priority did not expire, while on the Amex time priority lasts only until the next trade.
4. Note that size priority is different than pro rata sharing in that an entire incoming order may go to a single trader as opposed to be shared.
5. Tick size is the minimum price increment.
6. Assume a $0.125 tick size. Then in order to step ahead of an existing buy order, a trader must be willing to pay $12.50 more for each 100 shares he obtains. If the tick is only $0.01 then that same trader must only pay $1.00 more for each 100 shares he obtains.
7. Exchange Act Release No. 14416 at 4358.
8. A specialist is the designated primary dealer on a stock exchange. They have complete knowledge of all investor orders and generally have obligations to maintain orderly markets.
9. NASDAQ will be discussed in the next section.
10. Limit orders are orders to buy or sell a security at a specified price or better. Public customers submit limit orders, specialists and NASDAQ market makers submit quotes.
11. The quotes are predominately based on public orders. As evidence of this, consider that during 2003, NYSE specialists were involved in less than 20% of all trades.

12. The NASDAQ trade, through rule, only applied to an individual broker. That is, Broker X was not allowed to trade through any customer of Broker X, but was not prevented from trading through customer limit orders held by Broker Y.
13. The Midwest Stock Exchange traded some NASDAQ stocks, but was a distant third in market share.
14. See Barclay et al. (1998).
15. They use a Herfindahl–Hirschman Index as well as the number of nodes trading a stock to measure the degree of fragmentation before and after the switch to the NYSE and find that the gains in spread width and volatility are greater for firms experiencing more fragmentation prior to the decision to list on the NYSE.
16. The findings of Murphy and Weaver also suggest that TSX members eventually began using order routing technology that allowed them to capitalize on the TSX crossing priority rule. This action dampened the impact of consolidation and spreads widened again.
17. See Amihud (2002), Amihud and Mendelson (1986) and Amihud et al. (1997), among others.
18. Taken from Madhavan et al. (2005).
19. Recall that NYSE specialists are involved in less than 20% of all trades.
20. Assume that there are 100 shares offered at $19,200 at $19.05, 100 at $19.10, and 300 at $19.15. A market order to buy 500 shares will take out the sell orders from $19 to $19.15, leaving the best offer at $19.15 until new offers to sell arrive. This is sometimes referred to at walking the book.
21. Assume a deeper market of 600 shares offered at $19. Then a 500 share order will not move the price.
22. Recall that a similar situation existed on NASDAQ before the adoption of the OHR.

Abstract

A strategy that buys past winners and simultaneously sells past losers based on stock performance in the past 3–12 months is profitable in the U.S. and the European markets. This survey paper reviews the literature on the momentum strategy and the possible explanations on the momentum profitability.

46.1 Introduction

"Trend is your friend" is a very popular saying in Wall Street since the inception of stock markets. However, whether this momentum trading strategy that is based on buying past winners and selling past losers is really profitable was controversial until recently. Jegadeesh and Titman (1993) were the first to comprehensively test the profitability of the momentum trading strategy based on the past 3- to 12-month performance. They document that momentum strategies implemented in the U.S. market from 1965 to 1989 generated a positive profit of about 1% per month over 3- to 12-month holding periods. In their recent follow-up study, Jegadeesh and Titman (2001) find that momentum strategies continued to be profitable after 1990 with past winners outperforming past losers by about the same magnitude as in the earlier period.

Rouwenhorst (1998) studied individual stock momentum with a sample of stocks listed on 12 European exchanges during the period from 1978 to 1995. The results demonstrate that momentum profits of about 1% per month are not limited to a particular market, but instead they are present in all 12 markets in the sample. Rouwenhorst (1999) also finds that momentum strategies are profitable although not to the same degree in 20 emerging markets. Chui et al. (2002) examine the profitability of momentum strategies in eight different Asian countries: Hong Kong, Indonesia, Japan, Korea, Malaysia, Singapore, Taiwan, and Thailand. Their evidence indicates that the momentum effect is present in all of the Asian countries except Korea and Indonesia but it is generally weak and is statistically significant only for Hong Kong, Malaysia, Singapore, and Thailand for the pre-crisis period. Interestingly, they find that the Common Law/Civil Law distinction provides an indicator of whether or not a market exhibited a momentum effect prior to the financial crisis. Asness et al. (1996), Chan et al. (2000), and Richards (1997) document that momentum strategies are profitable when implemented on stock market indices.

Recently Moskowitz and Grinblatt (1999) find that industry momentum strategies, which advocate buying stocks from past winning industries and selling stocks from past losing industries, appear to be highly profitable. This industry momentum accounts for much of the profitability of individual stock momentum strategies in the United States. Once returns are adjusted for industry effects, momentum

e-mail: johnwei@ust.hk

profits from individual equities are significantly weaker, and for the most part are statistically insignificant. However, Grundy and Martin (2001) have a different view on the contribution of industries to individual momentum profits. They argue that a 1-month interval between the ranking period and the holding period has a pivotal role in the conclusion that industry momentum strategies are profitable. Industry momentum strategies are significantly profitable only when the ranking period is contiguous to the holding period as documented by Moskowitz and Grinblatt (1999). However, given a 1-month interval between the two periods, industry momentum strategies cannot earn significant profits. Grundy and Martin (2001) conclude that industry effects are not the primary cause of the individual momentum profitability. Liu and Wei (2004) document that industries in 12 European markets, like their counterparts in the U.S. market, also explain the profitability of individual momentum strategies. Specifically, past winner industries outperform past loser industries by more than 1% per month. However, unlike their counterparts in the U.S. market, industries cannot solely explain the profitability of individual momentum strategies in 12 European markets. In addition, industry momentum strategies can still earn significant profits even with a 1-month interval between the formation and holding periods.

46.2 The Implementation of Momentum Strategies

To show how to implement a momentum strategy, we use a momentum strategy that is based on the past 6-month performance with a 6-month holding period an illustration. Specifically, to form momentum portfolios, at the end of each month all securities in each of the samples are ranked in ascending order based on the past 6-month cumulative returns with dividends. The securities in the bottom 10% (or 20% or 30%) are assigned to the loser (denoted as "L") portfolio, while those in the top 10% (or 20% or 30%) are assigned to the winner (denoted as "W") portfolio. These portfolios are value-weighted using the market capitalization of the security at the end of the ranking month as the weight. Each of these portfolios is held for 6 months.

To reduce the effect of nonsynchronous trading and the bid–ask bounce, Jegadeesh and Titman (1993) suggest that we measure returns on these portfolios 1 month after the ranking takes place. If a security has any missing returns during the holding period, we replace them with the corresponding value-weighted market returns. If the returns on the security are no longer available, we rebalance the portfolio in the month the security is deleted from our database. Excess returns on a security are calculated as the returns on that security minus the risk-free rate, which we

assume is equal to the 1-month government short-term rate, such as the U.S. Treasury bill rate.

To increase the power of our tests, we construct overlapping portfolios. The winner (loser) portfolio is an overlapping portfolio that consists of the "W" ("L") portfolios in the previous 6 months. The returns on the winner (loser) portfolios are the simple average of the returns on the six "W" ("L") portfolios. For instance, the January return on the winner portfolio is the simple average of the January returns on the "W" portfolios that are constructed from June to November in the previous year. The momentum portfolio we examine is the zero-cost, winner-minus-loser portfolio.

46.3 Explanations of Momentum Profits

Jegadeesh and Titman (2001) discuss three potential explanations for the profitability of momentum strategies and examine the performance of momentum portfolios over longer horizons in order to differentiate between these hypotheses. The three explanations include: (1) stock prices underreact to information, (2) there is a delayed overreaction to information, and (3) the profits are generated from cross-sectional differences in expected returns.

The first two explanations are consistent with some recent behavioral models. For example, the underreaction explanation is consistent with the Barberis et al. (1998) model where a "conservatism bias" can lead investors to underreact or underweight new information. In the case with a pure conservatism bias, once the information is fully incorporated in prices, there is no predictability in stock returns. In this case, the expected post-holding period returns are zero.

There are a number of behavioral models that are consistent with a delayed overreaction. Barberis et al. (1998) also discuss this possibility and describe what they call the "representative heuristic," which suggests that investors may overly extrapolate a firm's past extraordinary earning growths into the future, and hence overreact to positive (or negative) information that is preceded by positive (or negative) information. In addition, Daniel et al. (1998) argue that delayed overreaction can arise because of "self-attribution (or cognitive) bias." That is, investors tend to become more overconfident when their stock picks become winners and take more aggressive positions that push up the prices of winners above their fundamental values. Finally, Hong and Stein (1999) propose a model with two groups of investors: informed investors and technical traders, who do not fully take into account the actions of each other. As a result, information is incorporated slowly into stock prices, providing a potential profit opportunity for technical traders. These traders, however, tend to push prices of past winners above their fundamental values. In each of these behavioral models, prices tend

to eventually overreact to information and then reverse when prices eventually revert to their fundamentals. All these behavioral models predict the expected post-holding period returns to be negative.

The third explanation is consistent with an efficient market where stocks have different expected rates of return because of different risk exposures. In particular, Conrad and Kaul (1998) emphasize that there would be some evidence of momentum even if there were no time-series variation in expected returns since stocks with high-(low) expected returns would be expected to have the highest (lowest) returns in adjacent periods. This explanation suggests that the profits from a momentum strategy should be the same in any post-ranking period.

To test these competing hypotheses, we normally examine the post-holding period returns of momentum portfolios beyond the first year after formation, typically up to 5 years. The empirical evidence from the U.S. (Jegadeesh and Titman, 2001) and Asian markets (Chui et al., 2002) appears to support the delayed overreaction explanation. That is, the returns on the momentum portfolio eventually reverse to negative 2–5 years after formation. In addition, Fama and French (1996) find that the Fama–French (1993) three factors cannot explain the momentum profits in the United States.

46.4   Momentum Profits and Firm Characteristics

Firm characteristics such as book-to-market ratios, market capitalization, and turnover have shown to have the ability to predict the cross section of expected stock returns in the United States. Behavioral models also predict that momentum profits are related to firm characteristics.

The overconfidence model by Daniel et al. (1998) suggests that momentum profits arise because investors are overconfidence. Daniel and Titman (1999) argue that overconfidence is likely to influence the perception of investors relatively more, when they analyze fairly vague and subjective information, and use book-to-market ratios as a proxy for information vagueness. Consistent with their hypothesis, they find that momentum profits are negatively related to the firm's book-to-market ratio in the U.S. market. Chui et al. (2002) also find similar results for Asian markets.

Trading volume or turnover could also proxy for information vagueness. As suggested by asymmetric information models (see for example, Blume et al., 1994), trading volume reflects investors' disagreement on a stock's intrinsic value. The more vague the information used to value the firm, the more disagreement among the investors, and hence, the greater the trading volume. Therefore, the momentum effect should be stronger for firms with high trading volume or turnover. Lee and Swaminathan (2000) find that

momentum profits are indeed higher for firms with high turnover ratios in the U.S. market. Chui et al. (2002) also find similar results for Asian markets.

In contrast, Hong and Stein (1999) predict that stocks with slow information diffusion should exhibit stronger momentum. Hong et al. (2000) provide tests that support this prediction. In particular, except for the very smallest decile stocks, the profitability of momentum investment strategies declines sharply with firm size. Hong et al. (2000) also look at momentum profits and analyst coverage and find that holding size fixed-momentum strategies work better for stock with low analyst coverage. In addition, they find that the effect of analyst coverage is greater for stocks that are past losers than for stocks that are past winners. They conclude that their findings are consistent with the gradual information diffusion model of Hong and Stein (1999).

Equilibrium Credit Rationing and Monetary Nonneutrality in a Small Open Economy

47

Ying Wu

Abstract

This paper modifies the well-known Mundell–Fleming model by adding equilibrium credit rationing as well as imperfect asset substitutability between bonds and loans. When the representative bank's backward-bending loan supply curve peaks at its profit-maximizing loan rate, credit rationing can be an equilibrium phenomenon, which makes credit-dependent capital investment solely dependent upon the availability of customer market credit. With credit rationing, an expansion in money and credit shifts the IS curve as well as the LM curve even in a small open economy under a regime of fixed exchange rates, and the magnitude of offset coefficient between domestic and foreign asset components of high-powered money is less than one. In contrast, if there is no credit rationing, imperfect asset substitutability between bonds and loans per se cannot generate the real effect of money in the same model.

47.1 Introduction

Is money non-neutral in a small open economy with international capital mobility and a fixed exchange rate regime? Can monetary policy affect real output in these circumstances? The answer to these questions is widely construed to be negative because the money supply has lost its role of a nominal anchor in this case.[1] In the orthodox money view, it is the interest rate that serves as the channel through which monetary policy affects the real sector of an economy; however, because the interest rate channel of monetary policy is highly correlated with exchange rates, and because the monetary authority commits to the maintenance of the fixed exchange rate, the consequent foreign

exchange intervention by the monetary authority using official reserves necessarily washes out any real effect of the monetary policy that it has previously initiated. The same approach is used in most of the existing literature on small open economies, such as the traditional IS/LM analysis, which holds a lopsided view of bank liabilities and bank loans. Other than influencing interest rates via manipulating deposits (a money asset and bank liability), banks have no active leverage to play with; the role of bank loans escapes unnoticed since bank loans are grouped together with other nonmonetary assets such as bonds.

In contrast to the money view, the credit view of monetary transmission mechanism rejects the notion that all nonmonetary assets are perfect substitutes. According to the credit view, due to information asymmetries between borrowers and lenders in financial markets, banks can play a particular role in reducing information costs. It is financial intermediation that can help a firm with risk-sharing, liquidity, and information services; as a result, a large number of

firms have in fact become bank dependent. Furthermore, although a rise in the loan rate increases, *ceteris paribus*, the bank's expected return by increasing interest payment when the borrower does not default, it lowers the bank's expected return by exacerbating adverse selection and moral hazard problems, and thus raising the probability of default. Hence, the bank's loan supply curve can be backward-bending, and credit rationing may occur as an equilibrium phenomenon.[2] Credit rationing per se makes monetary credit availability rather than interest rates in order to be the conduit for the real effect of money, therefore providing a major theoretical underpinning for the effectiveness of monetary policy under fixed exchange rates.

This paper begins with a study of the loan market setting with asymmetric information as a micro-foundation for consumption and investment, and further develops a macromodel of a small open economy under a fixed exchange rate regime with perfect capital mobility in the bond market and imperfect asset substitutability between bonds and loans. As far as the credit view is concerned, this paper in spirit is close to Bernanke and Blinder (1988), who address the credit channel of monetary policy in a variant of the IS/LM model. They differ in several regards, however. Unlike Bernanke and Blinder, the model in this paper incorporates the possibility of equilibrium credit rationing while maintaining the assumption of imperfect substitutability of bank loans and bonds. With imperfect substitutability between bonds and bank loans, this paper nests both credit-rationed and credit-unrationed equilibrium regimes. Additionally, by placing the credit channel of monetary policy in the setting of a small open economy, this chapter allows the possibility to explore the relevance of the "monetary policy ineffectiveness" proposition in the existing mainstream small-open-economy literature.

Partly based on Wu (1999) by drawing on its microeconomic foundation setting, this study has made important and substantial revisions to its macroeconomic analysis. With the credit availability channel, this study shows that money in the fixed exchange rate model is not completely endogenous by appealing to the asymmetry between customer market credit and auction market credit under equilibrium credit rationing.[3] Incorporating bank credit into the fixed exchange rate model leads to two fundamental changes. First, it extends the scope for monetary policy to affect economy from the standard interest rate channel to the one including the bank lending channel and balance sheet channel as well; the latter two conduits can be independent of changes in interest rates. Second, and more importantly, monetary policy will no longer be deemed impotent since it can directly "shift" the goods market as well as money market equilibrium schedules in such a way that the targeted real effect could be achieved while the fixed exchange rate is sustained.

The next section presents the analytical structure of bank behavior and credit market; the following two sections explore how credit market conditions determine macroeconomic equilibrium in an open-economy IS/LM framework, and demonstrate the real impacts of monetary shocks through its credit channel, respectively. The final section concludes the study.

47.2   Bank Behavior and Credit Market

It is well known that due to the credit risk associated with adverse selection and moral hazard problems a banking firm has an inverse U-shaped loan supply curve with a backward-bending portion. This section essentially modifies the pedagogical model in Christopher and Lewarne (1994) by extending the spectrum of bank investment into the portfolio selection between bonds and loans.

The representative banking firm is assumed to hold exactly the required amount of reserves, and allocate all of its excess reserves between the two bank assets: bonds and loans. Thus, it chooses loans, l, subject to its balance sheet identity, to maximize its profits from lending

$$\Pi = \theta(\rho)l\rho + b_{\mathrm{b}}r - dr - \frac{\gamma}{2}l^2$$
$$\text{s.t. } b_{\mathrm{b}} + l = (1-k)d, \tag{47.1}$$

where ρ is the loan rate, $\theta(\rho)$ the probability of loan repayment, γ the cost parameter of servicing loans, b_{b} denotes bonds held by the banking firm, r is the interest rate on bond, d represents total deposits, and k is the required reserve ratio for deposits.

Here, the low-risk or risk-free interest rate on bond holding is assumed to be the same as the interest cost of taking in deposits. Thus, deposits and bonds are perfectly substitutable assets to depositors so that they pay the same expected return per dollar. The key characteristic of the bank profit is that the repayment probability depends on the loan rate. Following the existing literature on equilibrium credit rationing, an increase in the loan rate makes it more likely for borrowers to default, hence the repayment probability is a decreasing function of the loan rate.[4] In addition, the representative bank takes the flow of deposits as given when making its portfolio decisions. Substituting the balance sheet identity into the bank's objective function and maximizing it with respect to l yields the banking firm's loan supply curve

$$l^S = \frac{\theta(\rho)\rho - r}{\gamma}. \tag{47.2}$$
Fig. 47.1 Loan repayment probability

Several implications of the loan supply curve can be derived. First, the loan supply curve is backward bending. The co-movement of the loan rate and loan volume hinges on the elasticity of the odds of repayment with respect to the loan rate. Only when the repayment probability is inelastic can a positive relationship exist between the loan rate and loan volume. To be specific, consider a linear repayment probability $\theta(\rho) = \phi - \Psi\rho$, where ϕ is the autonomous repayment probability determined by noninterest factors such as the liquidity of balance sheet positions, and Ψ measures the sensitivity of the repayment probability to the loan rate ($0 < \Psi < \phi \leq 1$). Figure 47.1 depicts the loan repayment probability function. In the case of linear loan repayment probability function, the loan volume supplied increases with the loan rate until the loan rate achieves $\phi/2\Psi$, after which a higher loan rate actually reduces the loan volume. In Figure 47.1, the loan rate at which the loan supply curve begins to bend backward points to the repayment probability halfway to its maximum within the possible range.

Substituting $\theta(\rho) = \phi - \Psi\rho$ into Equation 47.2 and differentiating Equation 47.2 with respect to r, ϕ, Ψ, and γ produces the responses of loan supply to the parameters of servicing loans. In particular, an increase in the bond interest rate, r, *ceteris paribus*, makes bond holding more attractive; accordingly, banks will reduce loans and hold more bonds. Another interpretation for the decrease of bank loans is based on the equivalence between the bond interest rate and the deposit rate: the higher the interest expenses of raising loanable funds by issuing deposits, the higher the economic cost of making loans. Next, banks tend to issue more loans when the autonomous repayment probability, ϕ, is higher, for example due to borrowers' increased net worth. In addition, the larger the sensitivity of the repayment probability to the loan interest rate, Ψ, the more deteriorating the problems of adverse selection and moral hazard, thus it is more likely for credit rationing to occur. Finally, an increase in the cost of servicing loans, γ, also tends to reduce loans as long as the expected return per dollar of loans exceeds the corresponding real opportunity cost.

Applying the envelope theorem to the representative bank's profit function in Equation 47.1 while incorporating Equation 47.2 and $\theta(\rho) = \phi - \Psi\rho$ generates the following marginal bank profit with respect to the loan rate:

$$\frac{d\Pi(\rho)}{d\rho} = \frac{1}{\gamma}\left[2\Psi^2\rho^3 - 3\Psi\phi\rho^2 + (2\Psi r + \phi^2)\rho - \phi r\right]. \quad (47.3)$$

The bracket term on the RHS of Equation 47.3 is a cubic expression but two of the three roots are degenerated solutions at which loans are zero, respectively; thus the only feasible root for Equation 47.3 is $\rho^* = \phi/2\Psi$, at which the bank's expected profits are maximized. Recall that the bank's loan supply curve peaks exactly at the same loan rate as the profit-maximizing loan rate here. Therefore, the result suggests the existence of equilibrium credit rationing. Further, the result for profit-maximizing loans also imply that the loan interest rate exceeds the bond interest rate such that $\rho > \sqrt{r/\Psi} > r$, which captures the existence of risk premium of bank lending, and therefore signifies the imperfect substitutability between loans and bonds.

Moving from the representative bank to the aggregate banking system, the aggregated bank balance sheet identity shows $B_b + L + R = D$, where B_b represents the bonds held by banks, D denotes deposits, and L is the volume of loans. For simplicity, currency is abstracted from the model. The required reserve of the banking system, R, constitutes the monetary authority's liabilities, or high-powered money, H, which are generated by its acquisition of bonds (B_a) and foreign exchange (F). The high-powered money in this framework is composed of exclusively required reserves; the money supply can be expressed by H/k.

Suppose there are n banks, with the representative bank's supply of loans specified in Equation 47.2 aggregating, and which generates the total supply of loans. A structural view of the aggregated balance sheet of banks suggests that if banks allocate a fraction of their excess reserves into loans and the rest into bonds, the aggregate supply of loans is given by $\varepsilon(1 - k) \cdot (H/k)$, where ε represents the ratio of loans to excess reserves. Accordingly, the share of loans in excess reserves must characterize the banks' loan-making behavior and it is thus actually a function of the same set of variables that determine aggregate supply of loans.

$$L^S = \varepsilon(\rho, r, \phi, \Psi, \gamma, n)\left(\frac{1-k}{k}\right)H,$$
$$? - + - - + \quad (47.4)$$

where the symbols underneath each of the arguments in $\varepsilon(\bullet)$ denote the signs of the partial derivatives associated with

them. For simplicity, it is assumed that bank credit is the only debt instrument for firms to finance their investment; investment demand and the demand for bank loans are taken to be equal.[5] Thus, aggregate demand for loans is negatively related to the loan interest rate, and its standard linear form is

$$L^D = \alpha - \beta\rho. \tag{47.5}$$

Indeed, as demonstrated by the existing literature on markets in disequilibrium, the loan market may or may not be at the market-clearing equilibrium.[6] Nevertheless, unlike disequilibrium economics, the loan quantity traded in the market is not uniformly characterized by the minimum of demand and supply sides. Loan rationing can arise in an unrestricted market setting flawed only by plausible information asymmetries; the loan rate can always freely adjust to a level consistent with market forces driven by the profit-maximization incentives. Therefore, credit rationing could exist at the profit-maximizing loan rate, $\rho^* = \phi/2\Psi$, and sustain as an equilibrium phenomenon. The excess demand fails to drive the loan rate upward because the associated credit risk would reduce banks' profits; however, if at the same loan rate there is an excess supply, the loan interest rate will adjust downward to clear the loan market, since holding excess reserves does not add to profits at all.

Consider the demand for and supply of loans specified in Equations 47.4 and 47.5, respectively, then the equilibrium interest rate in the loan market is given by

$$\rho = \begin{cases} \dfrac{\phi}{2\Psi}, & \text{if } L^D \geq L^S \text{ at } \dfrac{\phi}{2\Psi}; \\ \min\left(\rho_1,\ \rho_2 | L^D = L^S\right), & \text{if } L^D < L^S \text{ at } \dfrac{\phi}{2\Psi}, \end{cases} \tag{47.6}$$

where ρ_1 and ρ_2 are the two roots of the quadratic equation given by $L^D = L^S$. Recall that $\rho^* = \phi/2\Psi$ is the loan rate that corresponds to the maximum quantity of loans. If an excess supply exists at ρ^*, L^D must cross L^S once at a loan rate below ρ^* and once at a loan rate above ρ^*. Since ρ^* is the profit-maximizing loan rate, the bank has no incentive to raise the loan rate to any level above ρ^*, and credit is then rationed at the equilibrium. On the other hand, the profit-maximizing loan rate is not attainable if there is excess supply at ρ^*, since the bank cannot force the firms to borrow in excess of the amount that maximizes their profits. It follows that if a bank cannot maximize its profit at ρ^* due to deficient demand, the best attainable outcome for the bank is to allow a downward adjustment in the loan rate until the loan market clears. Therefore, the loan quantity traded is at the market-clearing equilibrium level if the market interest rate of loans is below the banks' desired level, ρ^*; otherwise, it would be determined by supply at the profit-maximizing loan rate.

47.3 Macroeconomic Equilibrium

Assume that investment is solely dependent on the availability of bank credit, and investment demand is equivalent to the demand for loans. Based on the analytical results in the preceding section, there is an implicit positive relationship between the interest rates on loans and bonds, which can be explicitly expressed as $\rho = \lambda(r)$. If credit demand is not rationed in the loan market, we have $I(\rho) \equiv L^D[\lambda(r)]$, with $I' = L'^D \lambda' < 0$, however, with credit rationing, investment demand is totally determined by the aggregate supply of loans.

47.3.1 Case for Credit Rationing

With credit rationing, the quantity of loans effectively traded is given by L^S as specified in Equation 47.4. In this case, the monetary authority can help loosen credit rationing through open market purchases: the nonbank public, which sells bonds to the monetary authority deposits the proceeds into banks, and the loan supply increases with the deposits. The rationing situation improves and the resulting increase in output increases money demand, and thus imposes upward pressure on the interest rate and the exchange value of the domestic currency. This in turn relieves the money market of the adjustment burden resulting from the monetary authority's commitment to the fixed exchange rate under the circumstances of open market purchases. Therefore, following the monetary authority's open market purchases, although there are market forces to purchase foreign bonds, which leads the monetary authority to sell foreign reserves, the authority's operation on foreign reserves does not fully sterilize its open market operation on domestic bonds so that its net effects are to expand loans and increase output.

Credit rationing enhances originally existing imperfect asset substitutability between bonds and loans, and lending to domestic capital investment under rationing is expected to be more preferable for holding foreign bonds. Without losing generality, a thought experiment could be to assume credit movement to be "segmented" in such a way that the goods market takes only credit expansion from open-market purchases on domestic bonds whereas it is asset portfolio adjustment rather than disinvestments in real capital goods that responds to any credit contraction from open-market sales on foreign bonds.[7] Hence, grouping Equation 47.4 with the equilibrium conditions of the goods market and the money market yields the following simple macroeconomic models:

$$Y = C(Y) + \varepsilon\left(\frac{1-k}{k}\right)B_a + X\left(Y,\ eP^f\right) \tag{47.7}$$

$$B_a + F = kl\big(Y, \ r^{\mathrm{f}}\big). \tag{47.8}$$

Note that the domestic price level is normalized at unity since price rigidity applies to the short-run macroeconomic model. Besides the derivatives property of L^{S} stipulated in (Equation 47.4), the other relevant derivatives in the above model satisfy the following conditions: $C'>0$, $X'_Y<0$, $i_Y > 0$, and $l'_r<0$. Equation 47.7 is the private-sector-only IS equation with the presence of the loan market in an open economy, where $C(\cdot)$ is consumption function, $\varepsilon[(1 - k)/k]$ B_a is the supply of loans available to investment from the monetary authority's open market purchases, $X(\cdot)$ is the net export function, e is the domestic currency price of foreign exchange, and P^{f} is the foreign price level. Equation 47.8 represents the "monetary" version of the open-economy LM equation (or the balance-of-payments equation). r^{f} is the foreign interest rate on bonds, which equals to r by perfect capital mobility in the bond market, and $l(\cdot)$ is the demand for money, increasing in income and decreasing in the interest rate.

There are three endogenous variables when credit rationing exists in the loan market: income Y, loan quantity L, and the international reserve component in the monetary base F. These are determined simultaneously in three equations (Equations 47.4, 47.7, and 47.8). Although money is partly endogenous due to perfect capital mobility in the bond market and the monetary authority's commitment to maintain fixed exchange rates, the endogeneity of money is not complete due to the credit channel of monetary transmission mechanism, and thus money is not completely neutral. Changes in the money supply serve to shift not only the LM curve but also the IS curve, so that the responsive change in money does not totally wash out the real effect generated by the monetary change associated with open-market purchases. Therefore, the credit channel rescues monetary policy from the charge of impotency.

47.3.2 Case for Nonrationing of Credit

In the regime in which loans are not rationed, both the loan quantity and the loan interest rate are endogenous variables in addition to income and the international reserves of the central bank. The general equilibrium system consists of the loan supply Equation 47.4, the monetary version of the balance-of-payments Equation 47.8, and two other basic equations given below:

$$Y = C(Y) + (\alpha - \beta\rho) + X\big(Y, \ eP^{\mathrm{f}}\big) \tag{47.9}$$

$$\alpha - \beta\rho = \varepsilon(\rho, r, \phi, \Psi, \gamma, n)\left(\frac{1-k}{k}\right)(B_a + F) \tag{47.10}$$

Equation 47.9 is the standard IS equation, unlike the credit-rationing counterpart in Equation 47.7, the interest rates play a role in the determination of income. In Equation 47.10, its LHS is the demand for loans, and the RHS the supply of loans. Equations 47.4, 47.8, 47.9, and 47.10 implicitly determine the equilibrium values of Y, L, ρ and F.

47.4 Comparative Static Analysis

The present section examines the responses of the equilibrium income, loan quantity, loan interest rate, and international reserve component of the monetary base to a monetary shock initiated through an open-market operation conducted by the monetary authority. These impacts vary with the rationing of credit.

Consider the credit-rationing model. Differentiating Equations 47.4, 47.7, and 47.8 with respect to L^{S}, Y, F, and B_a produces the following results:

$$\frac{\mathrm{d}L^{\mathrm{S}}}{\mathrm{d}B_a} = \frac{kl_Y\left(\varepsilon\frac{1-k}{k}\right)^2}{1 - C' - X'} > 0 \tag{47.11}$$

$$\frac{\mathrm{d}Y}{\mathrm{d}B_a} = \frac{\varepsilon\left(\frac{1-k}{k}\right)}{1 - C' - X'} > 0 \tag{47.12}$$

$$\frac{\mathrm{d}F}{\mathrm{d}B_a} = -1 + kl_Y \frac{\varepsilon\left(\frac{1-k}{k}\right)}{1 - C' - X'} < 0 \tag{47.13}$$

Under the fixed exchange rate system, changes in the official international reserves mirror the status of the balance of payments. Starting from the open-market purchase on the part of the monetary authority, the money supply (bank deposits) increases and multiplies through the money multiplier $1/k$ as high-powered money B_a increases. Banks usually tend to make more loans due to an expanded volume of deposits, and the increased loans relax the credit constraint facing the economy so that income rises, as measured in Equations 47.11 and 47.12. Finally, transaction demand for money also increases as a result of increased income but the generated money demand via the credit channel is less than the initial increase in money supply, i.e. the money created by the central bank outpaces the growth of money demand. The resulting excess supply of money must be spent on the purchase of foreign goods or financial assets. As the domestic residents exchange their domestic money for foreign money, the central bank loses international reserves and the money account of the balance of payment moves into a deficit ($\mathrm{d}F < 0$). The consequent money contraction will sustain until the disequilibrium in the money market disappears and

Fig. 47.2 Monetary non-neutrality under credit rationing in a small open economy with a fixed exchange rate
the balance of payments is back to equilibrium at the foreign interest rate, r^f.

Examining Equation 47.13 suggests that the credit channel per se plays a role to preserve the legacy of monetary policy. The increase in money demand generated from the credit-driven income expansion minimizes the adjustment burden that has fallen upon the official international reserves, so that the absolute value of the offset coefficient is less than 1 and monetary control is not completely lost.[8] The economics reasoning and the pertinent empirics suggest that the second term on the RHS of Equation 47.13 is a positive fraction, and in that term a large credit multiplier, $\varepsilon \cdot (1 - k)/k$, serves to reduce the magnitude of the offset coefficient given by Equation 47.13. Hence, the stronger the credit channel is, the more legacy of monetary policy can be reserved. However, without considering the credit channel, the endogenous change in foreign reserves would completely offset the initial change in the credit brought about by the central bank's open-market operations, and then the traditional result of monetary neutrality would follow.

Figure 47.2 summarizes the analytical results in a four-quadrant diagram. Quadrant I depicts the IS-LM-BP curves in the traditional general equilibrium framework, with the initial credit-rationing equilibrium as shown in Quadrant III, and Quadrant II depicts the linearized implicit function $\rho = \lambda(r)$. Consider an expansionary monetary policy initiated by the open market purchase. The LM curve shifts rightward initially to the position of the dashed line, causing the IS curve to shift in the same direction through the credit channel. This is reflected in Quadrant III by the downward shift of the aggregate loan supply curve, with the loan interest rate

remaining at the profit-maximizing equilibrium level. Due to the tight credit market, the resulting increase in loans directly translates into the corresponding increase in income at the full scale, as depicted in Quadrant IV.[9] The increased money demand mitigates the excess supply pressure on the money account of the balance of payments, though the equilibrium in the money market and foreign exchange market still entails a reduction of official international reserves held by the central bank. As a result, although the LM curve shifts backward away from its initial post-shock position as given by the dashed line, it does not shift all the way back to LM_0; instead, LM_1^{CR} meets IS_1^{CR} at Y_1^{CR} under the circumstances.

Now let us turn to the situation in which there is no credit rationing. Differentiating Equations 47.4, 47.8, 47.9, and 47.10 with respect to L, Y, ρ, F, and B_a generates the following comparative static results:

$$\frac{\mathrm{d}L}{\mathrm{d}B_a} = 0, \qquad (47.14)$$

$$\frac{\mathrm{d}Y}{\mathrm{d}B_a} = 0, \qquad (47.15)$$

$$\frac{\mathrm{d}\rho}{\mathrm{d}B_a} = 0, \quad \text{and} \qquad (47.16)$$

$$\frac{\mathrm{d}F}{\mathrm{d}B_a} = -1. \qquad (47.17)$$

As shown by the comparative static results in Equations 47.14, 47.15, 47.16, and 47.17, there is a sharp contrast between the cases of credit rationing and nonrationing of credit in terms of monetary neutrality and the effectiveness of monetary policy. In the absence of credit rationing, the credit channel can only operate through its impact on the loan interest rate. Nevertheless, the loan interest rate is directly related to the world interest rate through $\rho = \lambda(r)$, and the world interest rate cannot be influenced by a small open economy's monetary authority. Following an open-market purchase, once the domestic interest rate tends to decline from the level of the world interest rate, and thus the exchange rate may deviate from its par accordingly, the monetary authority is obliged to contract money and credit by selling its foreign reserves until the asset prices restore their initial equilibrium levels, therefore rendering the intended monetary expansion ineffective.

Conclusion

This paper has demonstrated that equilibrium credit rationing plays a role in preserving the legacy of monetary policy even under a fixed exchange rate regime with perfect international capital mobility. Under equilibrium credit rationing, credit-dependent investment transmits a monetary shock into changes in real income, and thus transaction demand for money, therefore sharing the adjustment burden of maintaining the fixed exchange rate, which would otherwise completely fall upon the official international reserves. The magnitude of offset coefficient becomes less than 1 since any expansion of domestic credit and its real effect is only partially offset by the associated monetary contractions happening through international financial portfolio investment. The degree of retained monetary autonomy depends on the magnitude of the credit multiplier under rationing.

When there exists equilibrium credit rationing, monetary contractions resulting from the monetary authority's endogenous open-market sale of foreign assets will take a conduit of portfolio disinvestments rather than real capital disinvestments. Therefore, the asymmetry between domestic real capital investment (customer market credit) and financial portfolio investment (auction market credit) in responding to impulses of open-market operations holds the key for monetary nonneutrality.

In contrast, incorporating credit market without credit rationing into analysis fails to rescue monetary policy from its neutrality in a small open economy committed to fixed exchange rates. The assumption of imperfect substitutability per se between auction market credit (bonds) and customer market credit (bank loans) is insufficient for monetary autonomy in the Mundell–Fleming model, though it is adequate for the modified IS-LM type model (Bernanke and Blinder, 1988) in which the features of small open economy and fixed exchange rates do not appear.

Notes

1. This line of analysis can be traced back to Fleming (1962) and Mundell (1963).
2. In their influential paper, Stiglitz and Weiss (1981) provide information-based analysis of equilibrium credit rationing. Blinder and Stiglitz (1983) further argue that monetary policy works through bank credit for there are no close substitutes for it at least as far as most medium and small firms with relatively high risk are concerned. For a comprehensive review of the credit view literature, see Kashyap and Stein (1993).
3. It is shown indeed in my earlier paper (Wu, 1999) that monetary policy can have real effects in both credit-rationing regime and the market-clearing regime if the central bank's foreign exchange reserves are independent of open-market operations. While considering the endogeneity of the monetary base, Ramírez (2001) argues that "monetary policy is still ineffective in influencing output under a fixed exchange rate, even with an operative credit channel." Nevertheless, in response to Ramírez (2001), this paper shows particularly how credit-rationing channel can save monetary policy from being charged with impotence even in a small open economy with complete capital mobility and fixed exchange rates.
4. As shown by Stiglitz and Weiss (1981) and others, the loan rate and intermediary charges may have both an adverse selection effect and a moral hazard effect on the risk of a pool of loans. Raising the loan rate shifts the mix of borrowers toward riskier firms and their projects to be financed by loans, thus reducing the lender's expected return. As a result, the intermediary may maximize its expected profits by setting an interest rate at a level that results in an excess demand for bank credit.
5. More generally, the demand side of the loan market is influenced by the interest rates on the two credit instruments, loans and bonds, as well as aggregate income, see Bernanke and Blinder (1988).
6. For studies on disequilibrium markets under price rigidity, see Barro and Grossman (1971), and Muellbauer and Portes (1978), among others.
7. Although the assumption of perfect capital mobility rules out the possibility of "home bias" that would otherwise explain the asymmetry between holding of domestic assets and holding of foreign assets, it is credit rationing that holds the key for the real effect of monetary policy here.

8. Some studies have provided the evidence for a certain degree of monetary autonomy under fixed exchange rates. For example, Cumby and Obstfeld (1983) and Rennhack and Mondino (1988) find that structural estimates of offset coefficients are less than one. Also, using Granger causality tests for a number of countries, Montiel (1989) and Dowla and Chowdhury (1991) report that some domestic financial aggregates like money and credit Granger-cause domestic real output.

9. For simplicity, the income multiplier effect is ignored here.

Abstract

Singapore's unique experience in macroeconomic management involves the government's engagement in a tripartite collective bargaining and its influence on the macroeconomic policy game in wages and exchange rates in response to inflation and output volatility. The period from the mid-1980s to mid-1990s features the policy game with a Nash equilibrium in the level of wages and exchange rates and a non-Nash equilibrium in wage growth and exchange rate appreciations. Based on the empirical evidence in this period, the models used in this study suggests that wage and exchange-rate policies are a pair of complements both at their levels (Nash equilibrium) and at their percentage changes (non-Nash equilibrium).

Keywords

Collective bargaining • Effective exchange rates • Inflation • Macroeconomic stabilization • Monetary Authority of Singapore • Nash equilibrium • National Wages Council • Unit labor cost • Unemployment • Wages

48.1 Introduction

Adverse supply shocks often pose a dilemma for the Keynesian approach to aggregate demand management: implementing expansionary monetary and fiscal policies tend to exacerbate inflation, whereas the laissez-faire policy stance is conducive to acute and prolonged unemployment before the economy restores its natural rate level of output. As an alternative means to avoid the predicament and cope with demand shocks as well as supply shocks, appropriate labor market policies, including wage policy, are recently gaining importance in macroeconomic management.[1] Nevertheless, wages tend to be sticky downward and it becomes difficult to attempt to reduce them due to the existence of strong labor unions or laws prohibiting such measures. The idea of instituting an agreement by unions and corporations to link wage growth with productivity growth, though attractive, often faces great political and economic challenges when it is put in practice.[2] Accordingly, in general, there is a dearth of research on the effectiveness of wage policy in an environment where other aggregate demand policies exist.

Singapore is an ideal case for the study of the effectiveness and dynamics of wage and exchange rate polices, not only because it has actively deployed wage policy in combination with exchange-rate policy for more than two decades but also because it has maintained a remarkable record of sustained economic growth with low inflation in a small open economy.[3] As a highly opened small economy, Singapore faces the challenges of "imported" foreign inflation as well as the wage-push inflation that results from rapid economic growth and labor shortage. The exchange rate and wage movements naturally become the two interrelated key factors in maintaining macroeconomic stability. Specifically, the wage policy manipulated by a tripartite collective bargaining institution known as the National Wages Council (NWC) has actually acted as an important complement to the country's exchange-rate policy controlled by the Monetary

Authority of Singapore (MAS) (Otani and Sassanpour, 1988; Wu, 1999).

The NWC is made up of representatives from the government, labor unions, and employer federations. Its main function is to select a wage policy that is not only agreeable by all three parties but also compatible with macroeconomic targets. Although the NWC's wage recommendations only sketch a guideline for negotiations between employers and employees, both public and private sectors usually accept and implement them rather smoothly. The resulting collective bargaining agreements often extend to nonunion workers as well. Labor unions in Singapore actively promote sound economic policies to their members and support restraints when needed. In this way, the wage council helps to reduce the frictions that information asymmetry and costly bargaining often cause in supply-side adjustments.[4] In coordination with the NWC's endeavor in achieving orderly wage settlements, the Monetary Authority of Singapore (MAS), as the other key player in Singapore's macroeconomic management, chooses the optimal exchange rate variation to cope with the dual inflationary pressures (i.e. the imported inflation and the inflation pushed by labor shortages) and to maintain the economy's competitiveness.

With its focus on the role of collective bargaining in macroeconomic management in Singapore, this study attempts to model the policy game of wage and exchange rate policies between the NWC and the MAS. The study starts with an analysis of the behavior of wage and exchange rate levels in the policy game and its empirics. It then further derives the MAS's exchange-rate response function and the NWC's wage response function in terms of percentage changes of the two policies, and analyzes two interplay patterns of the two response functions: the Nash game and the non-Nash game. For the non-Nash game, the study calibrates the analytical outcome in each of the three potential scenarios of the economy: inflation, recession, and the "Goldilocks" scenario (neither inflationary nor recessionary), and compares the simulation results with the actual quarterly growth paths under the two policy rules for the period from 1987:1 to 1996:4.

48.2 Complementarity of Wages and Exchange Rates

This section presents a policy-game model of wages and exchange rates at their levels.[5] For analytical simplicity, consider a composite product traded internationally under the purchasing power parity. Suppose that workers (employees) exert their influence in cooperation with the government and employers rather than through militancy. Wages are negotiated between firms and workers for each period. The representative firm hires workers to produce output q according to a production function $q(L) = L^{\phi}$ $(0 < \phi < 1)$. In wage negotiations, the

right-to-manage model is used, whereby workers bargain with employers for desired wages and employers choose employment at the negotiated wage level.[6]

Let W be the nominal wage, E the nominal exchange rate measured as units of the domestic currency per unit of a foreign currency, P^{f} the price of the tradable good in the foreign currency, L^{*} the level of employment demanded as a function of the real wage W/EP^{f}, i.e. $L^{*}(W/EP^{\mathrm{f}})$, and r the alternative source of income in real terms (unemployment compensation, for example) when the negotiating parties fail to agree upon W. Additionally, a constant-elasticity-of-substitution function $U(x) = x^{1-\gamma}/(1 - \gamma)$ $(0 < \gamma < 1)$ determines a representative worker's increasing and concave utility of the earned real income x. Denote the gain to the firm from agreeing to any given wage by $G_{\mathrm{F}}(W; EP^{\mathrm{f}})$ and the similar gain to workers by $G_{\mathrm{L}}(W; EP^{\mathrm{f}}, r)$, respectively. The role of the NWC is to incorporate any exchange-rate policy signal into the wage settlement process and guide the two negotiating parties to choose a wage level to maximize the generalized Nash product, a weighted geometric average of the gains to workers and to firms:

$$
\begin{aligned}
\left\{G_{\mathrm{F}}\left(W;\ EP^{\mathrm{f}}\right)\right\}^{S} & \left\{G_{\mathrm{L}}\left(W;\ EP^{\mathrm{f}},\ r\right)\right\}^{1-s} \\
&\equiv \left\{EP^{\mathrm{f}} q\left[L^{*}\left(\frac{W}{EP^{\mathrm{f}}}\right)\right] - WL^{*}\left(\frac{W}{EP^{\mathrm{f}}}\right)\right\}^{s} \\
&\quad \left\{L^{*}\left(\frac{W}{EP^{\mathrm{f}}}\right)\left[U\left(\frac{W}{EP^{\mathrm{f}}}\right) - U(r)\right]\right\}^{1-s}
\end{aligned}
\tag{48.1}
$$

where $s(0 < s < 1)$ is a weight reflecting the relative bargaining strength of workers. The variation of s traces out all the negotiated wages between the reservation level and the monopoly level in a Nash bargaining.

The first-order optimality condition determines the negotiated wage as

$$
w = e + p^{\mathrm{f}} + (1 - \phi)s + \frac{\phi}{1 - \gamma} + \ln\ r,
\tag{48.2}
$$

where the lower case variables denote their logarithms and the last two parametric terms are the result of Taylor's approximation. Equation 48.2 gives the wage negotiator's reaction function, which predicts the unit elasticities of wages with respect to the exchange rate and to the foreign price level, respectively. Furthermore, the Nash bargaining wage is greater the larger the workers' bargaining power (s), the higher the productivity (ϕ), the greater the unemployment compensation (r), and the greater the elasticity of marginal utility (γ).

Since employment is determined by the firms' demand for labor at the negotiated level of real wage, aggregate output, Y, is a decreasing function of the real wage.

Let L^A be aggregate employment and $F(L^A)$ aggregate output. Since the Cobb–Douglas production function determines aggregate output, it then follows that $Y = F(L^A(w - e - p^f)) \equiv h(w - e - p^f) = (w - e - p^f)^{\phi(\phi - 1)}$, with $h' = F'L^{A'} < 0$ and $\boldsymbol{h}'' = F''L^{A'} + F'L^{A''} > 0$. The monetary-fiscal authority has a loss function, Ω, which involves a cost associated with the inflation rate, $\pi \equiv De + Dp^f$ (D is the first-order difference operator) and the deviations of the current account from its target level, $\Theta > 0$ (See Wu, 1999 for the detailed derivation of current account balance, CA).

$$\Omega = \frac{a}{2}\pi^2 - (CA - \Theta). \qquad (48.3)$$

The current account surplus, unlike inflation, is favorable to the government so that a negative weight is attached to the second term in the loss function.[7] Inflation costs rise at an increasing rate with the rate of inflation, and the coefficient $a > 0$ measures the authority's intolerance of inflation. The authority's problem is to choose the exchange rate to minimize the loss function (Equation 48.3). The associated first-order condition is

$$a(De + Dp^f) + \frac{1 - c}{1 + \Psi}h'(w - e - p^f) + \frac{\Psi}{1 + \Psi}\tau\lambda = 0, \qquad (48.4)$$

where c is the marginal propensity to consume with respect to changes in disposable income, λ the weight for changes in the exchange rate in the balance payment account as opposed to changes in real foreign reserves ($0 < \lambda < 1$), and τ^{-1} is the sensitivity of exchange rate appreciation with respect to the balance of payments ($\tau^{-1} < 0$); in addition,

$$-1 < \Psi \equiv \frac{\beta}{1 - \lambda}\left[\frac{d}{\theta} - (\rho - r)\right] < 0,$$

where β is offset coefficient between domestic and foreign components of the monetary base ($0 < \beta < 1$), θ the proportion of CPF liabilities invested in government securities, d the marginal propensity to consume with respect to changes in real private saving, r the real interest rate on the government debt, and ρ the real rate of return on the debt-financed government overseas investment. Equation 48.4 implicitly determines the government's reaction function of the exchange rate to changes in the wage level, which, in turn, influences the wage that wage negotiators in the private sector demand. Therefore, the reaction function also indirectly conveys a signal of the government preference about the desired wage level with respect to the optimal exchange rate.

The wage-negotiators' reaction function (48.2), with the unemployment compensation parameter r being normalized to unity, and the government's reaction function (48.4) jointly determine the static equilibrium (e^*, w^*). The corresponding dynamic system in the neighborhood of (e^*, w^*) is

$$\begin{aligned} \dot{e} &= g_1(e, w) \\ &= -a(De + Dp^f) \\ &\quad - \frac{1 - c}{1 + \Psi}h'(w - e - p^f) - \frac{\Psi}{1 + \Psi}\tau\lambda, \end{aligned} \qquad (48.5)$$

$$\dot{w} = g_2(e, w) = e - w + p^f + (1 - \phi)s + \frac{\phi}{1 - \gamma} \qquad (48.6)$$

where $\dot{e}$ and $\dot{w}$ are the time derivatives of e and w. The dynamic system of the exchange rate and wages is stable as long as inflation is so expensive that a depreciation increases inflation costs more than strengthens competitiveness, that is,

$$a > \frac{1 - c}{1 + \Psi}h''.[8]$$

The empirical analysis with a vector error correction (VEC) model below demonstrates the robustness of the negative relationship between the exchange rate and wages obtained from comparative statics.

There are three variables: the logarithm of unit labor costs of all sectors (LULC,); the logarithm of the nominal effective exchange rate (LNEER); and the logarithm of the import price (LIMP) index compiled using the US dollar prices. The quarterly data are from the *International Financial Statistics*, ranging from 1980:1 to 1997:1. The augmented Dickey–Fuller test suggests that the three variables are all I(1) sequences.[9] The model is set with four-quarter lags by the conventional criteria, and the Johanson cointegration test suggests that there are exactly two cointegrating equations. Formally, after depressing the lagged difference terms, the estimated vector error correction model with four-period lags can be written as

$$DY_t = \alpha\beta'Y_{t-1} + \ldots + \varepsilon_t, \qquad (48.7)$$

where $\boldsymbol{DY_t} = (DLULC_t, DLNEER_t, DLIMP_t)'$, $\boldsymbol{Y_{t-1}} = (LULC_{t-1}, LNEER_{t-1}, LIMP_{t-1}, 1)'$, $\boldsymbol{\alpha}$ is a 3×2 matrix of the speed-of-adjustment parameters estimated as $[\boldsymbol{\alpha_1\alpha_2\alpha_3}]'$ with $\boldsymbol{\alpha_1} = (-0.10, -0.01)$, $\boldsymbol{\alpha_2} = (-0.03, -0.18)$, and $\boldsymbol{\alpha_3} = (0.09, 0.07)$, $\boldsymbol{\beta}$ is a 4×2 matrix of the normalized cointegrating vectors given by $[\boldsymbol{\beta_1\beta_2}]$ with $\boldsymbol{\beta_1} = (1, 0, -1.05, 0.09)'$, and $\boldsymbol{\beta_2} = (0, 1, 1.06, -9.46)'$, and $\boldsymbol{\varepsilon_t} = (\varepsilon_{t,LULC}, \varepsilon_{t,LNEER}, \varepsilon_{t,LIMP})'$ is the vector of white-noise disturbances.

The estimated cointegrating coefficients in the matrix β are significant with wide margins even at 1% significance level. According to the two cointegration equations, responding to an increase of 1% in import prices, wages increase by 1.05% and the exchange rate decreases by 1.06% in the long run. It follows that the purchasing power of wages in Singapore, measured in a basket of foreign currencies, has been rising in terms of imported goods. Derived from the two estimated cointegrating equations, the deterministic long-run equilibrium relationship can be described as

$$LULC = 9.28 - 0.99LNEER. \tag{48.8}$$

Equation 48.8 says that on average, each percentage of wage growth goes hand in hand with an approximately equal percentage of the Singapore currency appreciation vis-à-vis a basket of foreign currencies. The estimated speed-of-adjustment co-efficients in α reflect the dynamic adjustment mechanism and support the robustness of the long-term equilibrium relationship. Suppose that one-unit positive shock in import prices results in a negative deviation in the unit labor cost and a positive deviation in the exchange rate from the previous period's stationary equilibrium, respectively. In response to the disequilibrium errors, the growth of unit labor cost increases by 10% as suggested by the first adjustment coefficient in α_1 and the appreciation rate increases by 18% as suggested by the second adjustment coefficient in α_2. Both the speed-of-adjustment coefficients are significant at 1% level and convergent as well.[10]

48.3 Policy Games in Wage Growth and Exchange Rate Appreciation

This section explicitly models the tripartism between employers, union workers, and the government as the institutional foundation to form the NWC objective function.[11] Employers as a whole concern themselves with the competitiveness of their products in the world market, which hinges highly upon relative unit labor cost. Union workers, on the other hand, are interested in maintaining a balance between employment and the growth of real income. Unlike the groups of union workers and employers, the government targets healthy macroeconomic performance characterized by a balance between inflation and unemployment.

The growth rate of ULC (g_{ULC}) is a weighted average of the wage-growth rate (g_w) and the inflation rate (π): $g_{ULC} = (1 - \theta)g_w + \theta\pi$, where the weight θ is actually the parameter in a power function of labor productivity.[12] Denote the growth rate of foreign unit labor cost by $g_{ULC}{}^f$, then the expression $[(1 - \theta)g_w + \theta\pi + g_{NEER} - g_{ULC}{}^f]$ describes the evolution of relative unit labor costs. Formally, the NWC chooses the growth rate of wages to minimize its loss function

$$\begin{aligned} Loss_{NWC} &= \alpha_1[(1 - \theta)g_w + \theta\pi + g_{NEER} - g_{ULC^f}] \\ &+ \alpha_2\left[\frac{1}{2}(U - \hat{U})^2 + \frac{\gamma}{2}(\pi - \hat{\pi})^2\right] \\ &+ \alpha_3[\beta(g_w - \pi) + U] \end{aligned} \tag{48.9}$$

where $\hat{U}$ and $\hat{\pi}$ are the rates of unemployment and inflation targeted by the government, β the union workers' loss weight of real income relative to unemployment, γ the government's loss weight of inflation relative to unemployment, and α_1, α_2, α_3 represent the three weights associated with the loss functions of employers, the government, and union workers, respectively (these α's are the proxy parameters for the NWC participants' bargaining power). Note that $\gamma > 0$, $\beta < 0$, $\alpha_i > 0$, and $\Sigma\alpha_i = 1$. The first term in Equation 48.9 describes the cost to employers of deteriorating the relative unit labor cost, the second term represents the cost to the government when the unemployment rate and the inflation rate are off their targets, and the last term characterizes the cost to union workers when the real wage-growth rate falls or the unemployment rate rises.

The resulting optimal wage-growth rate responds to changes in economic conditions according to the following rule of reaction:

$$\begin{aligned} g_w &= \frac{A_1}{A_0} + \frac{A_2}{A_0}\pi_{Nop} + \frac{A_3}{A_0}g_{NEER} + \frac{A_4}{A_0}g_{w-2} \\ &+ \frac{A_5}{A_0}\pi_{-2} + \frac{A_6}{A_0}\pi_{OP-2} + \frac{A_7}{A_0}g_{w-3} \\ &+ \frac{A_8}{A_0}\pi_{-3} + \frac{A_9}{A_0}CPFC + \frac{A_{10}}{A_0}\hat{U} + \frac{A_{11}}{A_0}\hat{\pi} \end{aligned} \tag{48.10}$$

where $A_j(j = 0,1,\ldots, 11)$ are the functions of the structural parameters in the inflation equation, the unemployment-rate equation, and the unit-labor-cost growth equation; and the relative weights in the NWC's loss function (Equation 48.9). The values of these coefficient functions (A_j's) are sensitive to the model's economic structure.

The other policy-game player, the MAS, manipulates the exchange rate to improve the tradeoff between the imported inflation and the international competitiveness of Singapore's goods and services,[13] which depends upon the real effective exchange rate, i.e. the relative unit labor cost in this article. Although the benefits of currency depreciation to the export sector can be lost to imported inflation and the resulting wage-price spiral that builds up in the medium-term horizon of 3 or more years,[14] maintaining a strong currency is detrimental to the export sector in the short run.

Let g_E be the actual real appreciation rate, which equals $(1 - \theta)g_w + \theta\pi + g_{NEER} - g_{ULC}{}^f$, $\hat{g}$ the real appreciation

rate targeted by the MAS, and δ the weight loss of the deviation of the inflation rate from its target relative to the deviation of real appreciation. The MAS selects the nominal appreciation rate, g_{NEER}, to minimize its loss function:

$$\text{Loss}_{\text{MAS}} = \frac{1}{2}(g_E - \hat{g}_E)^2 + \frac{\delta}{2} + (\pi - \hat{\pi})^2 \qquad (48.11)$$

The first-order condition generates the MAS' rule of reaction:

$$\begin{aligned}
g_{\text{NEER}} = &\frac{B_1}{B_0}g_{\text{ULC}^f} + \frac{B_2}{B_0}g_w + \frac{B_3}{B_0}g_{w-2} + \frac{B_4}{B_0}\pi_{-2} \\
&+ \frac{B_5}{B_0}\pi_{\text{NOP}} + \frac{B_6}{B_0}\pi_{\text{OP}-2} \\
&+ \frac{B_7}{B_0}\hat{g}_E + \frac{B_8}{B_0}\hat{\pi}
\end{aligned} \qquad (48.12)$$

where B_k's ($k = 0, 1, \ldots, 8$) are functions of the structural parameters and weights as A_j's in Equation 48.10.

In this model, the Nash game requires that a policy-making institution react to the optimal policy move made by the other policy-making institution as well as to the state of the economy. At the equilibrium, each institution's policy response is the best not only for the economy but also for the optimal policy of the other institution. Simultaneously solving the system of two non-Nash policy response functions, i.e. Equations 48.10 and 48.12 with the estimated structural coefficients, produces the Nash equilibrium characterized by the Nash appreciation rate of NEER (g_{NEER}^*) and Nash wage-growth rate (g_w^*) (both in their implicit forms) below:

$$\begin{aligned}
g_w^* = &f(\pi_{\text{NOP}}, g_{\text{ULC}^f}, \pi_{\text{OP}-2}, g_{w-2}, \pi_{-2}, \\
&g_{w-3}, \ \pi_{-3}, \ \text{CPFC}, \ \hat{g}_E, \ \hat{U}, \ \hat{\pi})
\end{aligned} \qquad (48.13)$$

$$\begin{aligned}
g_{\text{NEER}}^* = &h(\pi_{\text{NOP}}, \ g_{\text{ULC}^f}, \ \pi_{\text{OP}-2}, \ g_{w-2}, \\
&\pi_{-2}, \ g_{w-3}, \ \pi_{-3}, \ \text{CPFC}, \ \hat{g}_E, \ \hat{U}, \ \hat{\pi})
\end{aligned} \qquad (48.14)$$

In contrast, the non-Nash game simply takes feed-back from the state of the economy over a set of current and lagged state variables. Under this rule, any policy variable under the control of one institution does not react to a policy variable under the control of the other institution, i.e. only the currently observed appreciation rate enters the NWC's reaction function, whereas only the currently observed wage growth rate enters the MAS's reaction function. By estimating the structural coefficients in the non-Nash policy response functions for the NWC and MAS (i.e. Equations 48.10 and 48.12) the non-Nash game can be reduced to one in which the policy sensitivity depends only on the weighting parameters and policy targets.[15]

The stability of Nash equilibrium depends on whether the recursive relations determined by Equations 48.10 and 48.12 will yield a damped or an explosive time path of oscillation once the Nash equilibrium is disturbed. As shown in Wu (2004), the MAS response function 48.12 with estimated structural parameters is negatively sloped (for a reasonable value range of δ) and the similarly estimated NWC response function 48.10 is positively sloped and then the stability condition for the Nash equilibrium requires that the NWC response function be flatter than the MAS response function in the policy space (g_{NEER}, g_w). This condition is not satisfied, however. It, therefore, follows that with the appropriate estimates of structural parameters the Nash equilibrium is not stable and it is more meaningful to concentrate on the non-Nash equilibrium.

48.4 Complementarity of Non-Nash Wage Growth and Exchange-Rate Appreciation

Fixing the policy targets and assigning different values to the relative weights α_i, β, and γ makes it possible to simulate the computable time-paths of the non-Nash optimal appreciation rate, g_{NEER}, and the non-Nash optimal wage growth rate, g_w, over different economic scenarios. The purpose of simulation is to mimic non-Nash policy strategies and thus examine their sensitivity to the game-players' bargaining parameters and the policy stance.

There are three economic scenarios for simulation. In the benchmark case of Goldilocks economy (scenario 1), employees are equally concerned with real wage decline and unemployment ($\beta = -1$). The deviations from the government's targeted inflation rate are equally penalized as those from the targeted unemployment rate ($\gamma = 1$). And the MAS weights equally the deviations of the real exchange rate and inflation rate from their targeted levels ($\delta = 1$). In addition, the targeted rates of inflation and unemployment are, respectively, set at 2% and 3%, approximately, to reflect their long-term trend in the period; the targeted rate of real effective exchange-rate appreciation is chosen as 3% based on an 8-year moving average since 1988; and the targets specified above continue to apply to the other two economic scenarios. In a recession (scenario 2), the threat of recession prevents employees from demanding too much of real wage growth so that β falls in its absolute value ($\beta = -0.8$). The government's and the monetary authority's inflation weights assume a smaller value compared with the Goldilocks economy ($\gamma = \delta = 0.8$). The third scenario concerns an inflationary economy in which the monetary and fiscal authority weighs inflation more than the targeted real competitiveness ($\delta = 1.2$). In the NWC's loss function, the government's

Table 48.1 Correlation between wage growth and NEER appreciation[8]

	Actual	Non-Nash game simulation		
		Scenario 1	Scenario 2	Scenario 3
Correlation Coefficient	0.644	0.588	0.646	0.520

inflation target now also takes a greater weight than the unemployment target ($\gamma = 1.2$), and meanwhile, the inflation threat naturally raises the employees' concern with their real income ($\beta = -1.2$).

How do the growth rate of wages and the appreciation rate of exchange rates work together in Singapore? Table 48.1 presents the correlation coefficients between the NEER appreciation rate and non-Nash wage growth rate in all the three simulated scenarios as well as the actually observed correlation coefficient.[16] As in Table 48.1, all the simulation-based correlation coefficients are positive for the non-Nash regime. It follows that the two policies are complements in a non-Nash environment. Instead of responding optimally to each other, the non-Nash strategies work in such a way that at least one strategy acts independently without taking into consideration the intended target of the other. Hence, the two strategy variables tend to be relatively impartial in balancing and achieving their own targets. Furthermore, the observed positive correlation between actual wage growth and actual exchange-rate appreciation also matches the pattern for the simulated non-Nash outcome; it does so especially in scenario 2.[17]

48.5 Concluding Remarks

Singapore government's commitment to and continuous participation in the annual tripartite collective bargaining over wage growth signifies the effectiveness of the NWC's adaptable stance and flexible wage policy in smoothing out business cycles, which detracts from the conventional wisdom on wage rigidity and its macroeconomic implications. This paper explores the manner in which Singapore policymakers deploy wage policy in coordination with its exchange-rate policy to achieve macroeconomic stability. The theoretical result from the Nash bargaining in the level of wages and exchange rates suggests that in the long run, wages increase one percentage point for about every percentage point appreciation in the exchange rate, which is well supported by the cointegration and error-correction analysis.

Furthermore, for the period studied, Singapore's tripartite collective bargaining (through NWC) in the growth rate of wages seems to have followed the non-Nash game practice as opposed to the Nash game, as the latter is unstable. A number of structural factors could have actually prevented the NWC from optimally reacting to the best move made by the MAS, such as asymmetry in the decision-making frequency (high frequency on the part of MAS vs. the low frequency on the part of NWC), asymmetric information between policy players as well as their overlapping interests, or simply any barrier in the institutional structure that makes a full-fledged interaction between policy players unrealistic. Both the non-Nash rule simulation and actual observations indicate that the Singapore dollar exchange rate appreciation has acted as a complement to wage growth. Indeed, Singapore currency has exhibited a clear trend of appreciation vis-à-vis a basket of foreign currencies during economic upturns while the growth of labor earnings are rising and a trend of depreciation during economic downturns while the wage growth are declining.

Notes

1. In the euro area, particularly the familiar policy instruments like the exchange rate and money supply have ceased to be available at the national level while fiscal policy is also often constrained by the straitjacket that the budget deficit cannot exceed 3% of GDP, which renders more room for national wage policies (Calmfors, 1998; Wu, 1999; Lawler, 2000; Karadeloglou et al., 2000; Abraham et al., 2000).

2. The Council of Economic Advisers to the President in the US explicitly implemented income policies by imposing the general guidepost for wages from 1962 to 1965 for example (see Perry, 1967; Schultz and Aliber, 1966). The guidepost implicitly remained in practice from time to time in the 1970s as well. In the UK, the 1980s and 1990s saw a resurgence of interest in income policies due to rising unemployment. For an argument for wage policy, see Hahn (1983, p. 106).

3. The average annual GDP growth in Singapore over the last decade was greater than 7.5%, with an inflation rate of about 2% per year.

4. Singapore's system of national wage council has distinguished itself from the centralized collective bargaining in European countries in three aspects. First, unlike the intermittent European government involvement in wage negotiations, the Singapore government has continuously committed to its participation in the yearly tripartite wage-policy dialogue and agreements since the NWC was formed in 1972. Second, the smooth cooperation between union and nonunion workers and the NWC's effective tripartite coordination resulted in relatively small wage drifts (wage increases beyond those agreed upon in the central negotiations), which are in sharp contrast to the large wage drifts in Europe. Third, serving endogenously as an integrated part of

Singapore's macroeconomic management strategy, the NWC has reduced government reliance on exogenous instruments such as fiscal policy and other nonwage income policies, whereas many European governments normally approach interventions from outside the labor market.

6. For the right-to-manage model, see Nickell and Andrews (1983) and Oswald (1985).

7. For a similar formulation of the loss function, see Barro and Gordon (1983), and Agénor (1994).

8. The mathematical results of dynamics as well as comparative statics are available from the author upon request.

9. The augmented Dicky–Fuller values for LULC, LNEER, and LIMP are all below the 10% MacKinnon critical value in absolute terms.

10. With one standard-deviation innovation in import prices (LIMP) leading to a positive response of unit labor cost (LULC) and a negative response of the exchange rate (LNEER), both responses peak almost simultaneously at the fourteenth quarter after the shock; after that, both of them show a tendency to decay. Consistent with the cointegrating relationship discussed earlier, the pattern in which the wage response mirrors inversely the exchange rate response holds uniformly for all the possible orderings of the Choleski decomposition.

11. With kind permission of Springer Science and Business Media, the author has drawn on a longer version of Wu (2004) in the writings of this section and the next.

12. For the modeling and econometric specification of unit labor cost equation as well as price equation and unemployment equation, see the appendices in Wu (2004).

13. See Teh and Shanmugaratnam (1992) and Carling (1995) for the analyses of Singapore's monetary policy via exchange-rate targeting.

14. See Low (1994).

15. See Wu (2004).

16. For a given simulated scenario, the correlation coefficient does not vary with different bargaining cases because the parameters that reflect bargaining power are constant over time and they do not appear in the coefficients of any time-series variables in either Equation 48.10 or Equation 48.12.

17. Clearly, scenario 2 (recession) cannot characterize the 1987–1995 period in Singapore. The closest match of the simulated correlation with actual correlation in the scenario only suggests that there are some similarities between a recession period with low inflation or deflation and a high-growth period with low inflation. However, the simulation that is based almost exclusively on inflation-related parameters cannot distinguish one from the other.

Abstract

This paper purports to provide a theoretical underpinning for the problem of the Investment Company Act. The theory or the Le Chatelier Principle is well-known in thermodynamics: The system tends to adjust itself to a new equilibrium as far as possible. In capital market equilibrium, added constraints on portfolio investment in each stock can lead to inefficiency manifested in the right-shifting efficiency frontier. According to the empirical study, the potential loss can amount to millions of dollars coupled with a higher risk-free rate and greater transaction and information costs.

Keywords

Capital market equilibrium • Diversified mutual funds • Efficient frontiers • Investment Company Act • Le Chatelier principle • Markowitz model • Quadratic programming • Thermodynamics • With constraints • Without constraints

49.1 Introduction

In the wake of a growing trend of deregulation in various industries (e.g., utility, banking and airline), it becomes more and more important to study the responsiveness of the market to the exogenous perturbations as the system is gradually constrained. According to the law of thermodynamics, the system tends to adjust itself to a new equilibrium by counteracting the change as far as possible. This law, the Le Chatelier's principle, was applied to economics by Samuelson (1949, 1960, 1972), Silberberg (1971, 1974, 1978), and to a class of spatial equilibrium models: linear

programming, fixed demand, quadratic programming, full-fledged spatial equilibrium model by Labys and Yang (1996). Recently, it has been applied to optimal taxation by Diamond and Mirrlees (2002).

According to subchapter M of the Investment Company Act of 1940, a diversified mutual fund cannot have more than 5% of total assets invested in any single company and the acquisition of securities does not exceed 10% of the acquired company's value. This diversification rule, on the one hand, reduces the portfolio risk according to the fundamental result of investment theory. On the other hand, more and more researchers begin to raise questions as to the potential inefficiency arising from the Investment Company Act (see Elton and Gruber, 1991; Roe, 1991; Francis, 1993; and Kohn, 1994). With the exception of the work by Cohen and Pogue (1967), Frost and Savarino (1988), and Loviscek and Yang (1997), there is very little evidence to refute or favor this conjecture.

Empirical findings (e.g., Loviscek and Yang, 1997) suggest that over 300 growth mutual funds evaluated by Value Line show that the average weight for the company given the greatest share of a fund's assets was 4.29%. However, the Le Chatelier's Principle in terms of the Investment Company Act has not been scrutinized in the literature of

finance. The objective of this paper is to investigate the Le Chatelier principle applied to the capital market equilibrium in the framework of the Markowitz portfolio selection model.

49.2 The Le Chatelier Principle of the Markowitz Model

In a portfolio of n securities, Markowitz (1952, 1956, 1959, 1990, 1991) formulated the portfolio selection model in the form of a quadratic programming as shown below

$$min_{x_i x_j} v = \sum_{i \in I} x_i^2 \sigma_{ii} \sum_{i \in I} \sum_{j \in J} x_i x_j \sigma_{ij} \qquad (49.1)$$

subject to

$$\sum_{i \in I} r_i x_i \geq k \qquad (49.2)$$

$$\sum_{i \in I} x_i = 1 \qquad (49.3)$$

$$x_i \geq 0 \, \forall \, i \in I \qquad (49.4)$$

where x_i = proportion of investment in security i
σ_{ii} = variance of rate of return of security i
σ_{ij} = covariance of rate of return of security i and j
r_i = expected rate of return of security i
k = minimum rate of return of the portfolio
I and J are sets of positive integers
The resulting lagrange function is therefore

$$L = v + \lambda \left(k - \sum r_i x_{ij} \right) + \gamma \left(1 - \sum x_i \right) \qquad (49.5)$$

The solution to the Markowitz is well-known (1959). The lagrange multiplier of constraint Equation 49.2 assumes the usual economic interpretation: change in total risk in response to an infinitesimally small change in k while all other decision variables adjust to their new equilibrium levels, i.e., $\lambda = dv/dk$. Hence, the lagrange multiplier is of utmost importance in determining the shape of the efficiency frontier curve in the capital market. Note that values of x_{is} are unbounded between 0 and 1 in the Markowitz model. However, in reality, the proportion of investment on each security many times cannot exceed a certain percentage to ensure adequate diversification. As the maximum investment proportion on each security decreases from 99% to 1%, the solution to the portfolio selection model becomes more constrained, i.e., the values of optimum xs are bounded within a narrower range as the constraint is tightened. Such impact on the objective function v is straightforward:

as the system is gradually constrained, the limited freedom of optimum xs gives rise to a higher and higher risk level as k is increased. For example if parameter k is increased gradually, the Le Chatelier principle implies that in the original Markowitz minimization system, isorisk contour has the smallest curvature to reflect the most efficient adjustment mechanism:

$$abs\left(\frac{\partial^2 v}{\partial k^2}\right) \leq abs\left(\frac{\partial^2 v^*}{\partial k^2}\right) \leq abs\left(\frac{\partial^2 v^{**}}{\partial k^2}\right) \qquad (49.6)$$

Where v^* and v^{**} are the objective function (total portfolio risk) corresponding to the additional constrains of $x_i < s *$ and $x_i < s **$ for all i and $s^* > s^{**}$ represent different investment proportions allowed under V^* and V^{**} and abs denotes absolute value. Via the envelope theorem (Dixit, 1990) we have

$$\frac{d\{L(x_i(k), k) = v(x_i(k))\}}{dk} = \frac{\partial\{L(x_i(k), k) = v(x_i(k))\}}{\partial k}$$

$$= \lambda | x_i = x_i(k)$$
$$(49.7)$$

hence, Equation 49.6 can be rewritten as

$$abs\left(\frac{\partial \lambda}{\partial k}\right) \leq abs\left(\frac{\partial \lambda^*}{\partial k}\right) \leq abs\left(\frac{\partial \lambda^{**}}{\partial k}\right) \qquad (49.8)$$

Equation 49.8 states that the lagrangemultiplier of the original Markowitz portfolio selection model is less sensitive to an infinitesimally small change in k than that of the model when the constraints are gradually tightened. Note that the lagrange multiplier λ is the reciprocal of the slope of the efficiency frontier curve frequently drawn in investment textbooks. Hence, the original Markowitz model has the steepest slope for a given set of $x_i s$. However, the efficiency frontier curve of the Markowitz minimization system has a vertical segment corresponding to a range of low ks and a constant v. Only within this range do the values of optimum xs remain equal under various degrees of constraints. Within this range constraint Equation 49.2 is not active, hence the lagrange multiplier is zero. As a result equality relation holds for Equation 49.8. Outside this range, the slopes of the efficiency frontier curve are different owing to the result of Equation 49.8.

49.3 Simulation Results

To verify the result implied by the Le Chatelier we employ a five-stock portfolio with $x_i \leq 50\%$ and $x_i \leq 40\%$. The numerical solutions are reported in Table 49.1. An

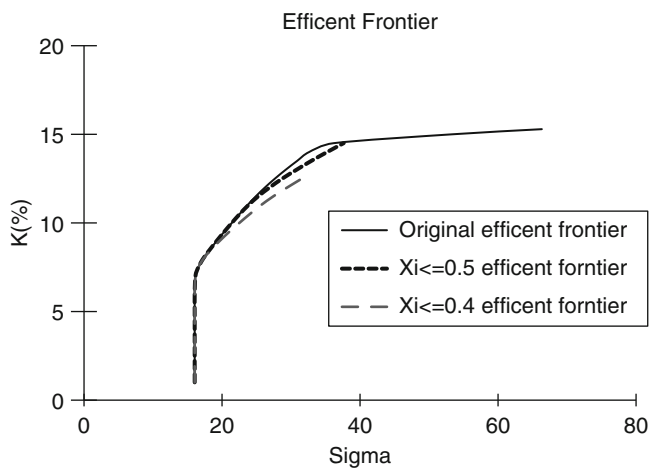
Efficent Frontier


examination of Table 49.1 indicates that the efficiency frontier curve is vertical and all optimum xs are identical between $0.001 \leq k \leq 0.075$. After that, the solutions of xs begin to change for the three models. Note that the maximum possible value for x_4 remains 0.4 throughout the simulation for $k > 0.075$ for the model with the tightest constraint $xi \leq 0.4$. In the case of $x_i \leq 0.5$, a relatively loosely constrained Markowitz system, all the optimum values of decision variables remain the same as the original Markowitz model between $0.01 \leq k \leq 0.1$. Beyond that range, the maximum value of x_4 is limited to 0.5. As can be seen from Table 49.1, the total risk v responds less volatile to the change in k in the original unconstrained Markowitz system than that in the constrained systems. In other words, the original Markowitz minimization system guarantees a smallest possible total risk due to the result of the Le Chatelier's principle: a thermodynamic system (risk-return space) can most effectively adjust itself to the parametric change (temperature or minimum rate of return of a portfolio or k) if it is least constrained.

49.4 Policy Implications of the Le Chatelier's Principle

As shown in the previous section, the efficiency frontier curve branches off to the right first for the most binding constraint of $x_i \leq s**$. Consequently, the tangency point between the efficiency frontier curve and a risk-free rate on the vertical axis must occur at a higher risk-free rate. As the value of maximum investment proportion for each stock s decreases, i.e., the constraint becomes more binding, there is a tendency for the risk-free rate to be higher in order to sustain an equilibrium (tangency) state. Second, one can assume the existence of a family of isowelfare functions (or indifference curves) in the v-k space. The direct impact of the Le Chatelier principle on the capital market equilibrium is a lower level of welfare measure due to the right branching-off of the efficiency frontier curve. In sum, as the constraint on the maximum investment proportion is tighter, the risk-free rate will be higher and investors in the capital market will in general experience a lower welfare level. In particular, the 5% rule carries a substantial cost in terms of shifting of the efficiency frontier to the right. The study by Loviscek and Yang (1997) based on a 36-security portfolio indicates the loss is about 1–2% points and the portfolio risk is 20–60% higher. Given the astronomical size of a mutual fund, 1–2% point translates into millions of dollars potential loss in daily return. Furthermore, over diversification would incur greater transaction and information cost, which speaks against the Investment ompany Rule.

Conclusion

In this paper, we apply the Le Chatelier principle in the thermodynamics to the Markowitz's portfolio selection model. The analogy is clear: as a thermodynamic system (or the capital market in the v-k space) undergoes some parametric changes (temperature or minimum portfolio rate of change k), the system will adjust most effectively if it is least constrained. The simulation shows that as the constraint becomes more and more tightened, the optimum investment proportions are less and less sensitive. Via the envelop theorem, it is shown that investors will be experiencing a higher risk-free rate and a lower welfare level in the capital market, if a majority of investors in the capital market experience the same constraint, i.e., maximum investment proportion on each security. Moreover, the potential loss in daily returns can easily be in millions on top of much greater transaction and information costs.

Abstract

This paper not only provides a comparison of recent models in the valuation of mortgage-backed securities but also proposes an integrated model that addresses important issues of path-dependence, exogenous prepayment, transaction costs, mortgagors' heterogeneity, and the housing devaluation effect.

Recent research can be categorized into two frameworks: empirical and theoretical option pricing. Purely empirically derived models often consider estimation of the prepayment model and pricing of the mortgage-backed security as distinct problems, and thus preclude explanation and prediction for the price behavior of the security. Some earlier theoretical models regard mortgage-backed securities as default-free callable bonds, prohibiting the mortgagors from exercising the default (put) option, and therefore induce bias on the pricing of mortgage-backed securities. Other earlier models assume homogeneity of mortgagors and consequently fail to address important issues of premium burnout effect and the path-dependence problem.

The model proposed is a two-factor model in which the housing price process is incorporated to account for the effect of mortgagor's default and to capture the impact of housing devaluation. Default is correctly modeled in terms of its actual payoff through a guarantee to the investors of the security such that the discrepancy is eliminated by assuming mortgage securities as either default-free or uninsured. Housing prices have been rising at unsustainable rates nation wide, especially along the coasts, suggesting a possible substantial weakening in house appreciation at some point in the future. The effect of housing devaluation is specifically modeled by considering the possibility that the mortgagor might be restrained from prepayment even if interest rates make it advantageous to refinance.

Mortgagors' heterogeneity and the separation of exogenous and endogenous prepayments are explicitly handled in the model. Heterogeneity is incorporated by introducing heterogeneous refinancing transaction costs. The inclusion of heterogeneous transaction costs not only captures premium burn-out effect but also solves the path-dependence problem. Finally, the model separates exogenous prepayment from endogenous prepayment, and estimates their distinct magnitudes from observed prepayment data.

This construction provides a better understanding for these two important components of prepayment behavior. The generalized method of moments is proposed and can be employed to produce appropriate parameter estimates.

50.1 Introduction

The main objective of this paper is to gain a better understanding of the valuation of mortgage-backed securities. Mortgage-backed securities have attracted unprecedented investor interest over the last decade, spurring tremendous growth in the market for this important financial instrument. There are over \$7.7 trillion worth of residential mortgage loans outstanding, an amount far exceeding the size of the corporate debt market. Approximately \$5.1 trillion worth of securitized mortgage-backed securities and CMOs are outstanding, and well over \$1.8 trillion new mortgage-backed securities and whole loans pools are issued each year for the past 3 years.[1] Mortgage-backed securities are extensively held by every class of institutional investor, including commercial banks, saving institutions, insurance companies, mutual funds, and pension plans.

An in-depth study of the valuation of mortgage-backed securities is of interest to financial economists because mortgage-backed securities have unique characteristics that are distinct from other contingent claims, such as monthly amortization, negative convexity, premium burnout, and path-dependence. This paper examines recent developments in the area of valuing mortgage-backed securities and proposes a model that accommodates these factors affecting the price of mortgage-backed securities.

The core issue in valuing mortgage-backed securities is the modeling of the prepayment behavior of mortgagors in the pool backing the security. Continuous-time option pricing methodology has been a popular method in the mortgage-backed securities valuation because of the obvious parallel between the call option and the right of a mortgagor to prepay. In order to model the mortgagors' prepayment behavior more realistically, recent theoretical models have added modifications to the original stock option pricing theory framework. The first of these modifications broadly accounts for prepayment due to reasons exogenous to financial consideration, such as moving and job changes. The second group of modification addresses transaction costs. The third considers heterogeneity among mortgagors, and the fourth group discusses the separation of exogenous prepayment and endogenous prepayment.

The observation that homeowners clearly do not prepay as objectively as option pricing models imply has motivated many researchers to add prepayment functions that allow prepayments for reasons that are exogenous to purely financial considerations. Such research includes the work of Dunn and McConnell (1981a, b), and Brennan and Schwartz (1985), and most of the prepayment functions have been arbitrary. The main drawback of adding an arbitrary prepayment function is that it does not aid in the identification of the factors responsible for prepayment behavior. Identifying these factors would go a long way toward enhancing the explanatory power of the model.

Applying the option pricing theory to the valuation of residential mortgage-backed securities, one can see a departure from the perfect market assumption when homeowners face transaction costs upon refinancing or defaulting. For this reason, Dunn and Spatt (1986) and Timmis (1985) add homogenous refinancing transaction costs in their models to adjust the prepayment speeds from those implied in the frictionless economic environment. Kau et al. (1993a) also add the transaction cost of default in their modeling of the probability of default for residential mortgages.

Addressing mortgagors' heterogeneity is a more complex matter. Many earlier models assumed homogeneity among mortgagors to avoid complexity in the pricing process. However, the assumption of mortgagors' homogeneity fails to address the issue of premium burnout which is an important empirical effect of homeowner heterogeneity. And this assumption also results in a path-dependent problem when numerically solving the optimal refinancing strategies backwards. The premium burnout effect is the tendency of prepayments from premium pools to slow down over time, with all else held constant. If a large number of mortgagors have already prepaid, those remaining are likely to have a relatively low probability of prepaying. Conversely, the smaller the number of previous prepayments, the higher the probability of

prepaying by the remaining mortgagors. The aforementioned path-dependent problem occurs because any mortgage pool contains a group of mortgagors who behave differently in their prepayment decisions: these mortgagors differ in their willingness or ability to prepay their loans under favorable circumstances. As a result, without knowing either the type of mortgagor or the entire path of interest rates from origination, backward optimization is not applicable because there is no way of knowing whether the earlier prepayment exercise is optimal.

Johnston and Van Drunen (1988), and Davidson et al. (1988) improve on the homogenous transaction cost model by introducing heterogeneous transaction models. They assume that different homeowners face different levels of refinancing transaction costs. In addition to the ability to capture the premium burnout, the inclusion of heterogeneous transaction costs also solves the path-dependent problem encountered when pooling individual mortgagors, who behave differently in their prepayment decisions.

Another common problem in existing models is the lack of differentiation between exogenous prepayment and endogenous prepayment. This lack of distinction between the two thereby precludes explanation of the interrelation between these important behavioral components. Endogenous prepayment refers to any prepayment decision that occurs in response to changes in underlying economic processes, such as the interest rate. Stanton (1990) incorporates an endogenous decision parameter that enables separate estimations of endogenous prepayment and prepayment for exogenous reasons. As a result, the explanatory power of the model is improved. In addition to the inclusion of the previously discussed modifications, our model introduces two adjustments. One is the treatment of mortgagors' right to default in the content of mortgage-backed securities valuation. And the other is the impact of the housing prices on prepayment behavior.

Although default has been modeled as a put option in the models of residential mortgages or commercial mortgage-backed securities, many earlier models have not incorporated it in the valuation of residential mortgage-backed securities. This is because government agency guarantees lead to the perception that securities are default-free. Default should be taken into consideration because there is a payoff difference between a guaranteed mortgage-backed security and a default-free security. The payoff from a guarantee in the event of default is the par amount rather than the market value of the security, thus producing an asymmetric return for investors.

In modeling default, we expand previous default-free models into a default-risky model in which the housing price process is included as a second-state variable. Default is explicitly modeled in terms of its actual payoff through a guarantee to the investors of the residential mortgage-backed security. This is in contrast to models for individual mortgages or commercial mortgages in which mortgages are neither insured nor guaranteed. Consequently, the payoff in the event of default in these cases is the value of the house. By correctly modeling the effect of default, our model reduces the discrepancy from assuming mortgage-backed securities as either default-free or uninsured.

The housing price process is incorporated in the model not only to account for the effect of default on security price, but also to determine its impact on the prepayment behavior of mortgagors. The effect of housing prices on prepayment is specifically modeled by considering the possibility that the mortgagor might be restrained from prepaying even if interest rates make it advantageous to refinance. This is because housing prices have fallen to the extent that the mortgagor is no longer qualified for refinancing.

The model we propose not only captures the fundamental characteristics of the mortgagors' prepayment behavior but it also combines parametric heterogeneity and variability of the decision parameter to the extent that our model can come closer than previous models in describing empirical prepayment behaviors.

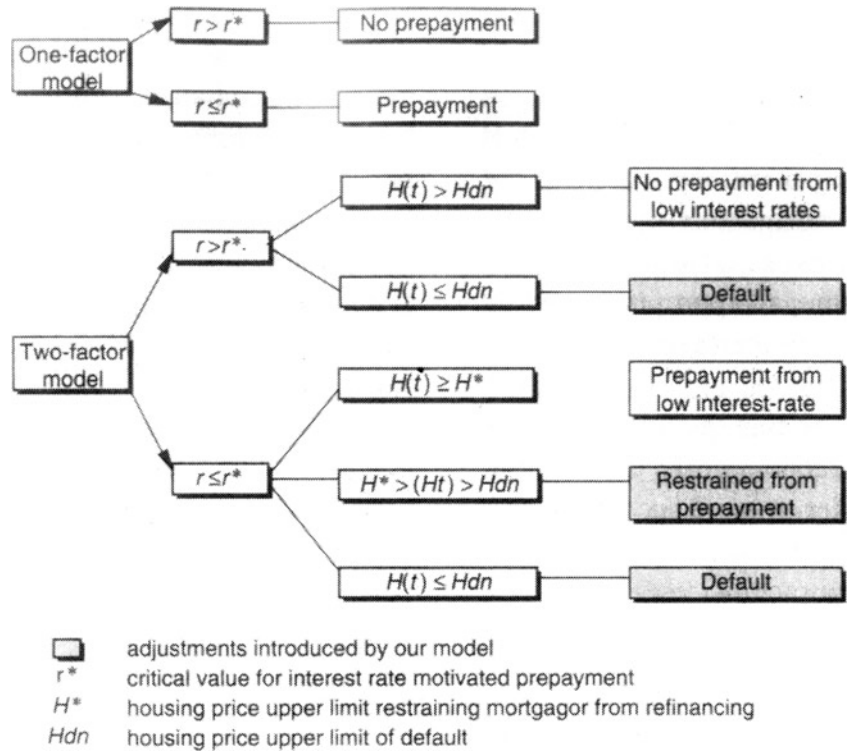
50.2 The Model

The central issue in valuing mortgage-backed securities is the treatment of prepayment uncertainty. The valuation model of mortgage-backed securities proposed here is based on the continuous-time option pricing methodology. This methodology treats the right of a mortgagor to prepay as a call option and the right to default as a put option. Modifications to the assumption of perfect capital markets and the principle that borrowers act to minimize the market cost of their mortgages are required to portray mortgagors' actual prepayment behavior in a more realistic manner.

According to Dunn and McConnell (1981a,b) and Brennan and Schwartz (1985), we allow mortgagors to prepay for reasons exogenous to purely financial considerations. In contrast to their models that assume arbitrary exogenous prepayment functions, our model utilizes the proportional hazard function and can be estimated from observable prepayment data.

To account for the fact that homeowners face transaction costs when they prepay or default on their mortgages, we follow Johnston and Van Drunen (1988). Consequently, we add heterogeneous refinancing transaction costs in our models to adjust the prepayment speeds from those implied in the frictionless economic environment. Following Kau et al. (1993a), we also add the transaction cost of default in modeling the effect of default.

Default has been modeled as a put option in the valuation of residential mortgages or commercial mortgage-backed

Fig. 50.1 Model trees


securities. However, many models have not incorporated default in the valuation of residential mortgage-backed securities because government agency guarantees lead to the perception that securities are default-free. Moreover, there is a significant difference between the payoff of a guaranteed mortgage-backed security and that of a default-free security. The payoff from insurance in the event of default is the par amount rather than the market value of the security, producing an asymmetric return for investors.

Kau et al. (1992) develop a two-factor model for both prepayment and default only in the context of evaluating individual mortgages, where mortgages are considered as uninsured. As discussed in the Chapter 50, the payoff from uninsured mortgages is the value of the house when the mortgage is defaulted. In our model, the payoff to the investor from default is explicitly modeled as insured mortgages. This eliminates the potential bias in the pricing of mortgage-backed securities.

A significant relationship between observed prepayment and housing prices data pointed out by Richard (1991) leads us a final adjustment of the two-factor model. The housing price process is brought in not only to account for the effect of default on security price, but also to determine its restraining effect on mortgagors' refinancing decisions.

Figure 50.1 outlines these differences between one-and two-factor models and the innovations presented in this study.

In the one-factor model, the prepayment decision responds to the level of interest rates. The two-factor model adds two additional termination outcomes that follow from the level of housing prices. At very low housing prices, the mortgagors may default regardless of the interest rate in order to cut their losses. Finally, the mortgagor might be restrained from prepaying even if interest rates make it advantageous to refinance. This occurs when the housing prices fall to the extent that the new loan cannot cover the costs of refinancing.

In addition to capturing these fundamental characteristics of the mortgagor's termination behavior, this model aggregates the underlying pool of mortgages according to the heterogeneity of transaction costs. And it is the specification of heterogeneous transaction costs that also solves the path-dependent problem displayed by pooled mortgages.

The following first section pertains to the modeling of termination decisions affected by exogenous and endogenous factors, housing prices, and transaction costs. The later section introduces our model, which is a two-factor pricing framework that provides exact security prices given underlying interest rate and housing prices processes, and precludes arbitrage opportunities.

50.2.1 Modeling Issues

50.2.1.1 Exogenous Prepayment

In practice, exogenous reasons for termination include factors such as relocation, death, divorce, or natural disasters. Exogenous prepayments are also known as

turnover prepayments. A hazard function is used to model exogenous prepayment as follows:

$$\pi(t) = \lim_{\delta t \to 0^+}$$

$$\Pr(\text{Exogeneous prepayment in}(t, t + \delta t)|$$

$$\times \frac{\text{No Prepayment prior to } t)}{\delta t} \quad (50.1)$$

There are numerous parametric methods used in the analysis of duration data and in the modeling of aging or failure processes. We use the exponential distribution in the model for its simplicity. The distribution is characterized by the constant hazard function

$$\pi(t) = \pi, \ t \geq 0 \text{ and } \pi > 0. \quad (50.2)$$

The probability that an individual has not prepaid for exogenous reasons until time t is given by the survival function $S(t)$,

$$S(t) = e^{-\pi(t)} = e^{-\pi t}, \ t \geq 0 \quad (50.3)$$

50.2.1.2 Endogenous Termination

A mortgage is terminated when mortgagors either prepay or default on their mortgages. Any termination which affects the cash flows passed through to the investors will have an impact on the price of the mortgage-backed securities. Throughout the model, endogenous termination is defined as any rational termination decision that occurs in response to underlying economic processes rather than personal considerations.

We assume that mortgagors maximize their current wealth, or equivalently, minimize their liabilities. Mortgagors' liabilities can be thought of as composed of three parts. The first part consists of owing the scheduled streams of cash flows associated with the mortgage. The second part constitutes their option to prepay at any time, which is equivalent to possessing a call option. And the third part consists of mortgagor's option to default, which functions as a put option. Option pricing theory is, therefore, an appropriate method for determining the value of mortgagors' mortgage liability.

A model of mortgage pricing should incorporate both refinancing transaction costs and default transaction costs in order to more accurately portray the decision-making processes of mortgagors. Although including transaction costs causes the resulting termination strategy to deviate from the perfect market assumption, the strategy still remains rational.

In order to derive the magnitude of endogenously determined termination, we follow Stanton (1990) and introduce ρ, which measures the frequency of mortgagors' termination decisions. The time between successive decision points is described as an exponential distribution. If we let T_i be one such decision point, and T_{i+1} the next, then

$$\Pr(T_{i+1} - T_i > t) = e^{-\rho t} \quad (50.4)$$

If mortgagors are continually re-evaluating their decisions, then the parameter ρ takes on a value of infinity. If mortgagors never make endogenous termination decisions and only terminate for exogenous reasons, then ρ takes on a value of zero. If ρ takes on a value between these limits, then this signifies that decisions are made at discrete times, separated on average by $1/\rho$.

Given this specification, the magnitude of endogenized termination can be estimated and studied. The contribution of this device is to separate the magnitude of endogenized termination from that of exogenous termination. It also serves to help understand the actual termination behavior of mortgagors. Without this specification, it would be difficult to know the proportion of termination from endogenous optimization decisions and the proportion due to exogenous factors.

Utilizing the definitions from Sections 50.2.1.1 and 50.2.1.2, we notice that the optimal exercise strategy immediately leads to a statistical representation of the time to terminate for a single mortgagor. If termination is due exclusively to exogenous factors, then the termination rate is π and the survival function is defined as in Equation 50.4. When termination occurs for endogenous reasons, the probability that the mortgagor terminates in a small time interval, δt, is the probability that the mortgagor neither prepays for exogenous reasons nor makes a rational exercise decision during this period. This survival function can be approximated by

$$S(t) = \begin{cases} e^{-\pi \delta t} \cdot e^{-\rho \delta t} = e^{-(\pi + \rho)\delta t} & \text{if endogenous termination} \\ e^{-\pi \delta t} & \text{if no endogenous termination} \end{cases}.$$

$$(50.5)$$

50.2.1.3 Transaction Costs and Aggregation of Heterogeneous Mortgages

The cash flows that accrue to the investor of a mortgage-backed security are not determined by the termination behavior of a single mortgagor, but by that of many mortgagors within a pool. To cope with the path-dependent problem caused by the heterogeneity within a pool of mortgages, we assume that the different refinancing transaction costs each mortgagor faces is the only source of heterogeneity. Although the costs of initiating a loan vary among different types of mortgages, some of the most common

costs borrowers face include credit report, appraisal, survey charges, title and recording fees, proration of taxes or assessments, hazard insurance, and discount points.

The transaction costs of individual mortgagors are drawn from a univariate discrete distribution, which allows for underlying heterogeneity in the valuation of the mortgage-backed security. A better way to choose the underlying distribution that represents this heterogeneity would be to look at summary statistics of transaction costs actually incurred by mortgagors when they refinanced. A discrete rectangular distribution is chosen for its simplicity and the task of determining which distribution improves the fit is left for future research.

The value of the security is equal to the expected value of the pool of mortgages weighted by the proportions of different refinancing transaction cost categories. Suppose that each X_i (the refinancing transaction costs faced by mortgagor i) is drawn from a discrete rectangular, or uniform distribution

$$\Pr(x = a + ih) = M^{-1}, \quad i = 1, \ldots, M \qquad (50.6)$$

Various standard forms are in use. For this application, we set $a = 0$, $h = RM^{-1}$, so that the values taken by x are $RM^{-1}, 2RM^{-1}, \ldots, R$. The upper bound R of the transaction cost is set at 10%. The distribution for the transaction costs is then defined as:

$$\Pr\left(x = i\frac{0.1}{M}\right) = M^{-1}, \quad i = 1, \ldots, M \qquad (50.7)$$

In principle, given any initial distribution of transaction costs, it is possible to value a mortgage-backed security backed by a heterogeneous pool of mortgages in a manner similar to the valuation of a single mortgage. If the value of individual mortgages is known, then the value of the pool is the sum of these individual values. When the value of individual mortgages is not known, but a distribution of transaction costs is generated that accounts for heterogeneity, the expected value of a pool of mortgages is the sum of the transaction cost groups times the probability of their occurrence in the pool.

Recall from Section 50.2.1.2 that for a given transaction cost X_i and state of the world, if any mortgagor finds it optimal to terminate, the hazard rate is the sum of the exogenous prepayment rate, π, and the endogenized termination rate, ρ. If it is not optimal to terminate, the hazard rate falls back to the background exogenous prepayment rate π.

Models that neither permit the estimation of ρ nor consider exogenous factors in the prepayment decision imply that $\rho = \infty$ and $\pi = 0$, and the single-transaction cost level predicts that all mortgages will prepay simultaneously. Adding heterogeneous transaction costs addresses the problem of path dependence, however, keeping the same parameter values still does not permit hesitation in the prepayment decision. Although prepayment rates fluctuate, in reality, they do tend to move fairly smoothly. The effect of setting ρ to a value other than ∞ is to permit a delay even when it is optimal to prepay. And prepayment need not occur at all if interest rates or housing prices change such that it is no longer optimal. The actual value of ρ determines how fast this drop occurs. Thus, combining parametric heterogeneity and variability of the parameter ρ would allow the model to come closer than previous rational models to describe empirical prepayment behavior.

50.2.2 A Model for Pricing Mortgage-Backed Securities

50.2.2.1 Termination Decision of a Single Mortgagor

The following is a model of rational prepayment behavior of mortgages that extends the rational prepayment models of Stanton (1990) and Kau et al. (1993b). Mortgagors may terminate their mortgages for endogenous financial reasons that include interest rates and housing prices, or for exogenous reasons. They also face transaction costs, which are used to differentiate mortgagors and solve the path-dependent problem. Mortgagors choose the strategy that minimizes the market value of the mortgage liability.

The following assumptions are employed:

1. Trading takes place continuously and there are no taxes or informational asymmetries.
2. The term structure is fully specified by the instantaneous riskless rate $r(t)$. Its dynamics are given by.

$$dr = \kappa(\mu_r - r)dt + \sigma_r\sqrt{r}dz_r \qquad (50.8)$$

3. The process to capture the housing price is assumed to follow a Constant Elasticity of Variance (CEV) diffusion process

$$dH = \mu_H H dt + \sigma_H H^{\gamma/2}dz_H, \qquad (50.9)$$

where μ_H, $\sigma_H > 0$, $0 < \gamma < 2$, and $\{z_H(t), t \geq 0\}$ is a standard Wiener Process, which may be correlated with the process $\{z_r(t), t \geq 0\}$. When $\gamma = 2$, the process is lognormal.

The underlying state variables in the model are the interest rate $r(t)$ and the housing price $H(t)$. By applying the arbitrage argument, the value of the ith mortgage liability $V^i(r,H,t)$ satisfies the following partial differential equation:

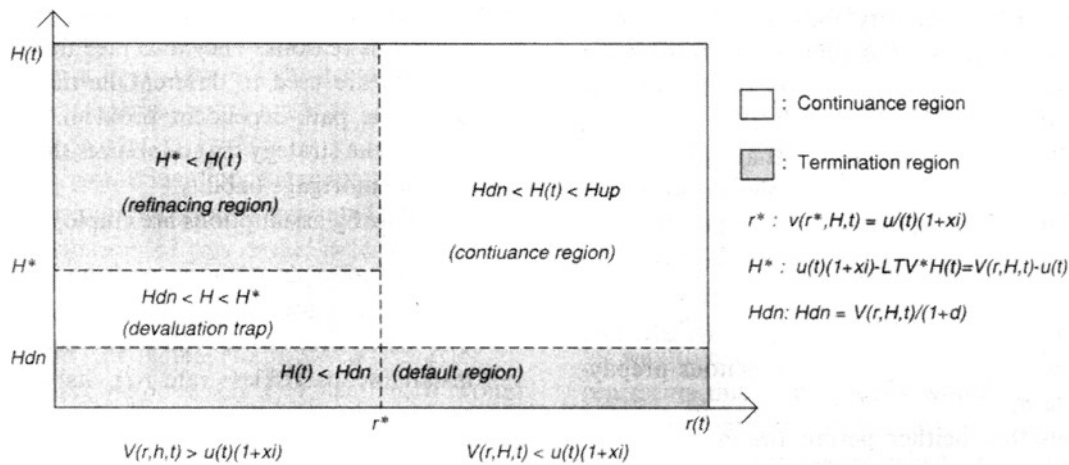
$$\frac{1}{2}\sigma_r^2 r V_{rr}^i + \rho\sigma_r\sigma_H\sqrt{r}H^{\gamma/2}V_{rH}^i$$
$$+ \frac{1}{2}\sigma_H^2 H^\gamma V_{HH}^i + [\kappa(\mu_r - r) - \lambda r]V_r^i$$
$$+ rHV_H^i + V_t^i - rV^i = 0, \qquad (50.10)$$


Fig. 50.2 Diagram of boundary conditions

where λr represents factor risk premium.

The value of the mortgage liability is also required to satisfy the following boundary conditions:

1. At maturity T, the value of a monthly amortization bond is equal to the monthly payment:

$$V^i(r, H, T) = MP$$

2. As r approaches infinity, the payoff of the underlying mortgage bond approaches zero:

$$\lim_{r \to \infty} V^i(r, H, t) = 0$$

Figure 50.2 summarizes the remaining conditions, which establish the boundaries of the various circumstances affecting the termination decision.

3. At any time t, the mortgage value satisfies the following conditions:

Let $V^i(r, H, t^+) = V^i(r, H, t + 1) + MP$, then

$$V^i(r,H,t) = \begin{cases} V^i(r,H, t^+) & \text{if } H(t) > Hdn \text{ and } U(t)(t + X_i) \\ & > V_i(r, H, t^+) \text{if continued} \\ U(t) & \text{if } H(t) > Hdn \text{ and } V^i(r, H, t^+) \\ & \geq (t)(l + Xi) \text{ if refinanced} \\ U(t) & \text{if } H(t) \leq Hdn \text{ if defaulted} \end{cases}$$

where $U(t)$ is the principal remaining at time t. Hdn is the boundary of default, defined as the housing price times the cost of default, or $Hdn = (V^i r, H, t^+)/(1 + d)$. X_i is the prepayment transaction costs for individual i and d is the transaction cost of default for all individuals. This boundary condition defines the default and refinancing regions in Figure 50.2. When housing prices fall so low that they are exceeded by the default cost-adjusted mortgage value, the mortgagor will exercise their put option by

defaulting. The refinancing region describes a situation in which the interest rate falls to the point where the mortgage value is greater than the refinancing cost-adjusted unpaid principal. In this case, the mortgagor exercises the call option by refinancing their loan. The value of the mortgage liability takes on the value of unpaid principal $U(t)$ unadjusted by transaction costs $(1 + X_i)$, because the refinancing costs are collected by the third party who services the mortgage.

4. To improve on the previous model, we have included the effect of housing prices on the termination decision

$$V^i(r, H, t) = V^i(r, H, t^+) \text{if } H^* > H(t)$$
$$> Hdn \text{ and } V^i(r, H, t^i) \leq U(t)$$
$$(1 + Xi) \text{ if restrained,}$$

where LTV is the loan-to-value ratio and H^* is determined at

$$U(t) + (1 + Xi) - LTV * H(t)$$
$$= V^i(r, H, t) - U(t). \tag{50.11}$$

This condition encompasses the devaluation trap. The devaluation trap occurs when housing prices fall between H^* and Hdn, where the costs of refinancing exceed its benefits. The mortgagor will be unable to refinance their loan, even though interest rates are advantageous, because they will have to pay the difference out of their pocket. And since the housing price remains above the default threshold, the mortgagor continues the mortgage. The present value of costs is determined by the left-hand side of Equation 50.11, that is the difference between the unpaid principal plus refinancing transaction cost and the new loan amount, which is the housing price times the loan-to-value ratio. The benefit of refinancing is given by the right-hand side

of Equation 50.11, i.e. the mortgage value minus the unpaid principal. The role of the loan-to-value ratio is important in determining the size of the devaluation trap. The higher loan-to-value ratios result in decreases in the range of the devaluation trap.

Working back 1 month at a time, we can value the ith mortgage liability $V^i(r, H, t)$ by solving Equation 50.10, given boundary condition 1 through 4. Given π and ρ, we can also calculate the probability that the mortgage is terminated in month t. Denote P_e the probability of termination if only exogenous prepayment occurs. Denote P_r the probability of termination if it is endogenous conditions that lead to a decision to terminate in month t. According to the survival function Equation 50.5, these termination probabilities are given by

$$P_r = 1 - e^{-(\pi+\rho)/12} \text{ if endogenous termination}$$
$$P_e = 1 - e^{-\pi/12} \text{ if no endogenous termination}$$

We can now calculate the expected value of a single mortgage liability. That is

$$V^i(r, H, t) = \begin{cases} (1 - P_r)V^i(r, H, t^+) + P_r U(t) \\ \text{(if endogenous ter min ation)} \\ (1 - P_e)^i(r, H, t^+) + P_e U(t) \\ \text{(if no endogenous ter min ation)} \end{cases}$$

50.2.2.2 Valuation of a Pool of Mortgages
To determine the value of the mortgage-backed security at any time t, as mentioned above, we can simply take the expected value of pooled mortgage liabilities

$$V(r, H, t) = \sum_{i=1}^{M} V^i(r, H, t) \times P(X_i = x) x \in (0, 0.1] \quad (50.12)$$

50.3 Estimation

A model for valuing mortgage-backed securities was described that permits the determination of the security's price for given parameter values describing exogenous and endogenous factors that contribute to the termination decision. The next logical step would be to estimate these parameter values from prepayment data. In this sector, the generalized method-of-moment technique is proposed for the estimation, where the termination probability at any given time t is required for equating the population and sample moments. In order to accomplish this, we must determine the model in terms of the probability rather than in terms of the dollar value of the security.

50.3.1 Determination of the Expected Termination Probability

In addition to equating the population and sample moments when the generalized method-of-moment technique is employed for the estimation, the calculation of termination probability is useful because it can also be utilized to determine the expected cash flows for any other mortgage-related securities, such as collateralized mortgage obligations. We first restate the procedure for determining the price in order to provide a comparison to the procedure for determining termination probability.

50.3.1.1 Procedure for Determining the Security Price
In this model, the uncertain economic environment a homeowner faces is described by two variables: the interest rate and the housing price. The term structure of the interest rate is assumed to be generated from the stochastic process described in Equation 50.8 and the process of the housing prices is represented in Equation 50.9. Assuming perfect capital markets, the present value $V^i(r, H, t)$ of the mortgage contract at time t is of the form

$$V^i(r, H, t) = \tilde{E}_t\left[e^{-\int_t^T r(t)dt} \bar{V}^i(T) \right], \quad (50.13)$$

where $\bar{V}^i(T)$ is the terminal value of the mortgage liability at expiration date T. This equation states that the value of the mortgage is equivalent to the discounted-expected-terminal payoff under the risk-neutral measure. By Girsanov's theorem, under certain circumstances, the change in measure merely produces a change in drift in the underlying diffusions. Consequently, one must substitute the risk-adjusted processes for the actual stochastic processes in Equations 50.8 and 50.9, which in this case are

$$dr = (\kappa\mu_r - (\kappa + \lambda)r)dt + \sigma_r d\tilde{z}_r \quad (50.14)$$

and

$$dH = rH\,dt + \sigma_H d\tilde{z}_H. \quad (50.15)$$

When the housing price process is transformed to its risk-adjusted form, the actual required rate of return on the house μH drops out of the equation. Therefore μH does not influence the mortgage and default option values. We know that the mortgage value $V^i(r, H, t)$ satisfies the partial differential equation specified in Equation 50.10. And thus, with the appropriate terminal and boundary conditions, the value of

the mortgage is determined by solving this partial differential equation (PDE) backwards in time.

50.3.1.2 Deriving the Expected Termination Probability of Mortgage *i*

In order to implement the parameter estimation, we are now concerned with the actual occurrence of termination instead of the dollar value of the mortgage. We begin the derivation of termination probability with the following definition:

$$
\begin{aligned}
P^i(r,\,H,\,t) = \Pr((r(\tau),\,H(\tau),\tau) \\
\in \text{ termination region of mortgage } i, \\
\text{for some} \\
\tau > t,\ \text{given}(r(t),\,H(t),\,t) = (r,\,H,\,t))
\end{aligned}
$$
(50.16)

where $(r,\,H,\,t)$ are the interest rate and housing price at current time t, while $P^i(r,\,H,\,t)$ is the probability that termination ever occurs beyond the current situation. The general theory of stochastic processes allows that such a probability satisfies the Kolmogorov backward equation

$$
\frac{1}{2}\sigma_r^2 r\, P_{rr}^i + \rho\sigma_r\sigma_H\sqrt{r}H^{\gamma/2}P_{rH}^i + \frac{1}{2}\sigma_H^2 H^\gamma P_{HH}^i \\
+ \kappa(\mu_r - r)P_r^i + \mu_H P_H^i + P_t^i = 0
$$
(50.17)

To describe the boundary and terminal conditions, we denote Ω for the part of (r, H, t) space outside the termination region, while $\partial\Omega$ forms the termination boundary. Using this notation, we have the terminal and boundary conditions

$$
P^i(r,\,H,\,T) = \begin{cases} 1/M & \text{if } (r,\,H,\,t)\in\partial\Omega,\ t\in(o,\,T) \\ 0 & \text{otherwise} \end{cases}
$$
(50.18)

These conditions merely state the obvious principle that termination has a probability of $1/M$ if the conditions lead to a decision to terminate and has a probability of zero if the mortgage continues. One might recall that a pool of the mortgagors is segregated according to a discrete uniform distribution with M groups. Hence, if the environment is within the termination region, the probability of termination of any given mortgage group is $1/M$, rather than one.

The determination of probability of termination does not involve discounting, and as such the non-homogeneous rV^i term from Equation 50.10 is excluded from Equation 50.17. Considering we are concerned with the actual incidence of termination and not the dollar value of the termination option, the real process in Equations 50.8 and 50.9 are used for $r(t)$ and $H(t)$ rather than the risk-adjusted processes.

Therefore, μH is required when the probability of termination is calculated although μH has no effect on the dollar value of mortgage liability. Solving the valuation problem from Equation 50.10 gives the index result of the termination region $\partial\Omega$, which consequently enters into the terminal conditions of Equation 50.17. These conditions are treated as a fixed-boundary problem in the solving of Equation 50.17, rather than as a free-boundary problem as in the solving of Equation 50.10.

Solving Equation 50.17 subject to the boundary conditions in Equation 50.18 yields the termination probability at any grid (r, H, t, X_i) for the individual mortgage liability i, called P_{it}. Recalling that the hazard rate for mortgage i from Equation 50.5 takes on a value of π if it is not optimal to terminate for endogenous reasons, and takes on a value of $(\pi + \rho)$ otherwise, and thus the expected termination probability for mortgage i, P_{it}^*, is calculated as

$$
P_{it}^* = P_e(1 - P_{it}) + P_r P_{it}.
$$
(50.19)

50.3.1.3 Determination of the Expected Termination Level of Pool *j*

Since the distribution of the refinancing transaction cost X_i is independent of the underlying stochastic processes, the expected termination for any given pool j is calculated by counting the proportion of terminations in each transaction cost group. If we denote P_{jt}^* as the expected termination probability for a given pool j, then

$$
\begin{aligned}
P_{jt}^* &= \sum_{i=1}^{M} P_{it}^* = \sum_{i=1}^{M} P_e(1 - P_{it}) + P_r\, P_{it} \\
&= P_e\left(1 - \sum_{i=1}^{M} P_{it}\right) + P_r \sum_{i=1}^{M} P_{it}
\end{aligned}
$$
(50.20)

Equation 50.20 permits us to calculate the expected termination probability for a given pool j without having to calculate the expected probability of each individual mortgage i.

50.3.2 Estimation Approach

50.3.2.1 Generalized Method of Moments (GMM)

The generalized method of moments procedure set out by Hansen (1982) and Hansen and Singleton (1982) has been widely used in financial market applications and in labor market application. The procedure is a limited-information method analogous to two-stage least squares. GMM provides a means of estimating parameters in a model by

matching theoretical moments of the data, as a function of the parameters, to their sample counterparts.

The usual way of proceeding is to identify error functions of the parameters and observable data which have an expectation of zero, conditional on the information available at the time the data are observed. That is, if we let θ_0 denote the true vector of parameter values, there are error functions $e_{it}(\theta_0)$, $i = 1, 2,\ldots, M$, satisfying the orthogonality conditions

$$E[e_{it}(\theta_0)|I_t] = 0, \qquad (50.21)$$

where e_{it} is a function of the parameters and of data up to and including time t and I_t is the information set at time t. This equation states that these error functions have a mean zero conditional on the information set at time t, when the functions are evaluated at the true parameter value. The implication is that the errors must be uncorrelated with the variables in the information set I_t, and thus, if z_{jt} is a finite dimensional vector of random variables that are I_t measurable, then by the law of iterated expectations

$$E[e_{it}(\theta_0)z_{jt}] = 0. \qquad (50.22)$$

If e is a $M \times T$ matrix, and z is $N \times T$, this can be rewritten as

$$E[g_t(\theta_0)] = 0, \qquad (50.23)$$

where g is the $MN \times T$ matrix formed by taking the direct product of e and z. This equation is the basis for the GMM technique. Suppose the sample counterpart of this set of population moments is the MN-vector valued function $g_T(\theta)$, which is defined by

$$g_T(\theta)_i = \frac{1}{T} \sum_{t=1}^{T} g_{it}(\theta). \qquad (50.24)$$

The usual GMM estimation procedure involves minimizing a quadratic form of the type

$$Q_T(\theta) = g_T(\theta)' \, Wg_T(\theta), \qquad (50.25)$$

where W is some positive-definite weighting matrix. This is usually done in two steps. First, take W to be the identity matrix and perform one minimization. Next calculate W_T, the sample estimator of

$$W_0 = (E[g_t(\theta_0)g_t(\theta_0)'])^{-1}, \qquad (50.26)$$

and use this as the weighting matrix in the second stage. As long as $W_T \to W_0$ almost surely, then the asymptotic variance matrix of the GMM estimator is

$$\sum_0 = \frac{1}{T} \left[(E[\partial g_t(\theta_0)'/\partial\theta])W_0(E[\partial g_t(\theta_0)/\partial\theta']) \right]^{-1} \quad (50.27)$$

In addition, the statistic $TQ_T(\hat{\theta})$, which is sample size times the minimized value of the objective function, $g_T(\theta)' Wg_T(\theta)$, is distributed as a chi-squared random variable with degrees of freedom equal to the dimension of $g_t(\theta 0)$ less the number of estimated parameters. This statistic provides a test of the over-identifying restrictions.

50.3.2.2 Moment Restrictions

The typical moment condition to use is the expectation of the difference between the observed prepayment level and its expected value, defined appropriately, equal zero. If we denote φ_{it} for the proportion of pool i prepaying in month t. The expected value of φ_{it}, t conditional on the information set at time t follows from above, assuming that the distribution of transaction costs among the mortgages remaining in the pool is known. If the termination probability of pool i at time t is P_{it}^*, then

$$E[\varphi_{it}|I_t] = P_e(1 - P_{it}^*) + P_rP_{it}^*, \qquad (50.28)$$

where $P_r = 1 - e^{-(\pi+\rho)\delta t}$, $P_e = 1 - e^{-\pi\delta t}$ are previously defined and P_{it}^* is calculated from the previous section.

It is possible to calculate unconditional moment conditions by multiplying these conditional moment conditions in Equation 50.28 and appropriate elements of the information set. Define the residual for pool i at time t as

$$e_{it} = \varphi_{it} - \bar{\varphi}_{it}. \qquad (50.29)$$

This satisfies the following expression:

$$E[e_{it}(\theta_0)|I'_t] = 0, \qquad (50.30)$$

where I'_t is a subset of the full information set at time t, which includes the interest rate path. Given this, it is possible to create more moment conditions as above. If z_{jt} is an element of I'_t, then $E[e_{it}z_{jt}] = 0$. However, z_{jt} may not be any variable that gives information about the actual sequence of prepayments. For example, setting z_{jt} equal to a lagged value of the prepayment level is not valid because the expected residual may be correlated with lagged prepayment levels. The implication of this is that there will be positive serial correlation in the residuals e_{it}. Hence, if the residuals are stacked in the usual way, averaging across time periods, one will have to deal with this serial correlation in calculating the appropriate standard errors for the GMM estimators.

To avoid the issue of serial correlation, the residuals can be stacked by averaging across pools, instead. Under the null hypothesis of independent pools, this way of stacking will

result in no correlation between the contemporaneous residuals from different pools. Therefore, by assuming that the mortgages are drawn from a well-behaved underlying distribution, the sample estimator W_T is still a consistent estimator of the optimal weighting matrix W_0, and the usual asymptotic standard error results are valid.

Conclusion

The valuation model of mortgage-backed securities proposed here is a model that extends the rational option pricing approach used by previous authors. This model is able to capture many important empirical regularities observed in prepayment behavior that have previously been modeled successfully using only purely empirically derived prepayment models. However, in these purely empirical models, estimation of the prepayment behavior and the valuation of a mortgage-backed security are often treated as completely separate problems. This model prevents *ad hoc* integration of the estimation of prepayment and the valuation of a mortgage-backed security, and links these two into a structured model. Therefore, this model can address economic questions that are beyond the scope of purely empirical models, while possessing a simple reduced form representation that allows estimation using observed prepayment data.

This integrated model captures the fundamental characteristics of a mortgage-backed security, such as exogenous prepayment, endogenous prepayment, transaction costs of refinancing and default, heterogeneity among mortgagors, and the issue of path dependence. In addition, the treatment of embedded options, the prepayment (call) option and the default (put) option, are modeled with care to accommodate more realistic aspects of a mortgagor's behavior. In particular, the payoff from the incident of default is modeled as an insured mortgage, so that the potential discrepancy in the pricing of the mortgage backed security is eliminated.

Another important innovation of the model is the explicit modeling of the housing devaluation effect that was the prevailing phenomenon in the early 1990s due to declined home prices. Over last several years, housing prices have been rising at unprecedented rates. A correction in the housing market is likely to occur in the near future and trigger a devaluation-induced prepayment slowdown. The term used for the devaluation effect is "devaluation trap" because the effect is activated only when housing prices fall to a degree at which the costs of refinancing exceed its benefits. The mortgagors are trapped and unable to refinance their loans even though interest rates are advantageous, because the new loans entitled from devaluated houses are no longer sufficient to cover the costs of refinancing.

Two constituents allow this model to come closer than previous models in describing empirical prepayment and price behavior. These are the incorporation of mortgagors' heterogeneity and the delaying of the rational prepayment decisions of mortgage holders. The heterogeneity of mortgagors is accomplished by introducing heterogeneous refinancing transaction costs. And the mortgagors' prepayment decisions are assumed to occur at discrete intervals rather than continuously, as was assumed with previous rational models. Hence, these two combined factors produce smoother prepayment behavior as observed in the actual data, and allow the model to generate prices that exceed par without requiring excessive transaction costs.

It is known that utilizing maximum likelihood as a means of estimating the parameters in parametric hazard models of prepayment is problematic, given the constitution of available prepayment data. Thus, by utilizing an alternative approach, the generalized method of moments, the model parameters can be estimated. This approach overcomes the problems associated with maximum likelihood in this setting.

The Impacts of IMF Bailouts in International Debt Crises

51

Zhaohui Zhang and Khondkar E. Karim

Abstract

The roles played by the IMF in international debt crises have long been considered controversial among both academics and policy makers. This study reviews the role of IMF bailouts in international debt crises. The literature shows that there is a statistically significant positive wealth transfer from the IMF to the international bank creditors during major event announcements. Further, the evidence indicates the existence of market informational efficiency and different pricing behavior of different groups of international bank creditors. A pertinent future research topic would be to examine whether IMF introduces the moral hazard problem into the international financial markets.

51.1 Introduction

"The roles played by the IMF in international debt crises have long been controversial among both academics and policy makers" (Zhang, 2001, p. 363). Financial crises in emerging markets and their contagion effects on the global financial system over the last two decades or so – Mexico, Argentina, Brazil, and Chile in 1982–83, Brazil in 1987, Mexico in 1990–1991 and again in 1994–1995, Argentina in 1995, Southeast Asia and Russia from 1997 to 1998, and the Brazilian crisis along with the U.S. Congressional debate over the increase in IMF quotas during 1997–1998 – have put the IMF under an intense spotlight in the global financial environment.

The current 182-member-country IMF was founded in July 1944 "in the hope that establishing a permanent forum for cooperation on international monetary problems would help avoid the competitive devaluation, exchange restrictions, and other destructive economic policies that had contributed to the Great Depression and the outbreak of war" (Fischer, 1998). The institution has evolved through the years along with a changing international financial community. Although the current role of the IMF is being challenged from both sides, by those who denounce it and those who want to expand it (Fischer, 1999), the IMF's objectives remain the same as when it was established.[1]

Who needs IMF bailouts? Two sharply opposing views confront each other. Criticisms of IMF policies can be found in David Malpass (1997, 1998), Shultz et al. (1998), Schuler (1998), Sacks and Thiel (1998), and in Wall Street Journal editorial articles (Editorial Articles, 1998a, b, c; 6 April, 15 April, 23 April), etc. Some even assert that the IMF caused the crises and therefore should be abolished. On the contrary, former U.S. Treasury Secretary Robert Rubin, Federal Reserve Chairman Greenspan (1998), former Treasury Secretary Summers (1998), and Rockefeller (1998), etc. argue that IMF loans are not only necessary but also the IMF needs to be strengthened.

The central discussion surrounding IMF bailouts is about the potential moral hazard problem in the international debt markets,[2] or put more explicitly, socializing costs versus privatizing gains. The negative views toward the IMF hold that bailout packages encourage imprudent lending behavior and that has resulted in a large amount of bad investments. There are opinions that these bad investments are largely responsible for the financial meltdowns in the troubled Asian countries. At the same time, the Western creditor banks are avoiding the negative ramifications of their bad investments in those countries by propping up their equity values with bailouts from the IMF using member countries' (both debtors and creditors) taxpayers funds. Arguably, those international bank creditors and troubled countries' domestic banks should bear the negative consequences caused by their imprudent lending and investments. As put in Radelet and Sachs (1998, pp. 51–52):

> The mechanics of the IMF loans merit special attention,. . .the (IMF) loan packages had the direct function of providing the central bank with resources to support the payment of debts falling due, while limiting the adverse effects of such repayments on the exchange rate. In the case of Korea, the linkage between the loan package and the repayment of the foreign debts was direct and fairly automatic. . .

The supportive views toward IMF bailouts mainly emphasize the insurance against the spread of the Asian crisis to other regions, i.e. containing the contagion effects. The following quote is again from Radelet and Sachs (1998, p. 52):

> The IMF has emphasized that the lending packages were intended to support stabilization, not merely to bail out foreign financial institutions. It had hoped that its role as a quasi lender of last resort would sufficiently restore market confidence that Asian governments would not need to draw down the full package of loans. If exchange rates could be stabilized and default avoided, the thinking presumably ran, private lending would revive. . .

According to this view, the IMF can deal with those troubled governments as a neutral, nonpolitical party; can contain social costs in those troubled countries as well as the danger of causing regional security problems; and can exert leverage to restructure those countries' economic systems toward a free-market system, therefore affecting and leading political systems toward more democratic ones.[3, 4]

While it is easy to understand why some people have a certain view of IMF bailouts, the role or the existence of the IMF itself, and the conditions the IMF enforces on bailout recipients are not well differentiated in the current discussions. The negative view toward bailouts sometimes claims that the existence of the IMF bailouts fosters imprudent lending behavior that in turn contributes to the development of currency crises. However, this view does not give the IMF credit for the condition that they lay out when they make a bailout to a country in crisis. Like the Federal Reserve's discount window policy, if the benefits of obtaining the funds are not as good as they look (i.e. the banks' books must be checked as a condition for obtaining the loan), then the incentives of committing moral hazard would be greatly reduced. The condition of the bailouts is nothing else but the counterparts of the incentives of committing moral hazard.

The following argument against the international critics of the IMF with regard to the moral hazard problem is extracted from Stanley Fischer's address[5]:

> To begin with, the notion that the availability of IMF programs encourages reckless behavior by those countries is far-fetched: no country would deliberately court such a crisis even if it thought international assistance would be forthcoming. The economic, financial, social, and political pain is simply too great; nor do countries show any desire to enter IMF programs unless they absolutely have to.

This point is further supported by the initial reluctance of South Korea to ask for the IMF bailout,[6] China's accelerated reforms in its financial sector to avoid similar crisis, and other similar arguments.

51.2 Literature Review

Event studies of international debt crises are abundant in the finance literature. These studies can be categorized according to several criteria. Based on subject matter, one group of studies (Cornell and Shapiro, 1986; Bruner and Simms, 1987; Smirlock and Kaufold, 1987) examines the impact of the "emergence" of less developed countries' (LDC) loan problems on the value of firms. Another group of studies analyzes the impact on firm values when the "solutions" to the LDC loan problems are proposed. The literature in this second group can be further divided into two subgroups according to whether the solutions are "direct" resolutions of the crises (Demirguc-Kunt and Huizinga, 1993; Madura et al., 1993; Unal et al., 1993; Zhang, 2001; Zhang and Karim, 2004), or "indirect" workouts of the crises (Billingsley and Lamy, 1988; Musumeci and Sinkey, 1990). Based on whether events "cluster" or not, or in other words, whether event windows are overlapping due to the characteristics of the occurrence of events, the event study methodology is also different. The clustering event analysis requires the estimation of the cross-sectional correlation between firms by employing multivariate analysis, such as in Smirlock and Kaufold (1987), Zhang (2001), and Zhang and Karim (2004). The more traditional nonclustering event studies use simple portfolio aggregation approaches, such as Fama et al. (1969).

Billingsley and Lamy (1988) studied the impact of the regulation of international lending on bank stock prices with regard to the U.S. legislative events in 1983. In the wake of the Mexican moratorium in August 1982, the United States passed the International Lending Supervision Act (ILSA),

and increased the U.S. quota in the IMF by $8.5 billion in 1983. While previous studies reveal that the impact of the passage of the ILSA on bank stock prices is negative, Billingsley and Lamy (1988) carried the study further to include the impact of the introduction of the Act in the Congress on bank stock returns. More importantly, the joint impact of the passage of the Act and the increase of the IMF quota for the United States were studied and found to be positive, though the perceived benefit of a greater IMF quota is diminished by the ILSA impact. Also, they find that the risk to the banking industry is decreased as a result of the legislative events. The authors assert that the economic significance of the legislative changes to bank stockholders depends on the perceived trade-off between the benefits of increased IMF subsidization of international loan risk and the reduced opportunity to pursue such risks under the ILSA.

The related hypotheses are: one, that investors did not perceive any of the considered legislative events to include economically material information; two, that investors did not view the exposed banks differently from nonexposed banks due to the legislative changes. They find that the United States support of the IMF event produced a daily positive excess return of about 1% for the stockholders, while the cumulative effect of the introduction of the ILSA has a negative impact on the stockholders as predicted. Both events were tested on the whole sample basis.

They also find that the nonexposed banks did not react significantly to the greater U.S. support of the IMF, while the exposed banks reacted in a vigorously positive manner. The "introduction" of the ILSA had no impact on either of the two subsamples. But the "passage" of the ILSA had a significant negative impact on exposed banks while there was no impact on nonexposed banks. Also, a significantly positive relationship was found to exist between the individual BHC stockholders' reactions and the extent of BHCs' Latin American loan exposures for both the passage of the IMF quota increase and the passage of the ILSA.

Demirguc-kunt and Huizinga (1993) studied the impact of "direct" official credits to debt countries on returns of foreign-exposed banks. The purpose of the paper is to infer from the movement of bank stock prices the implicit transfer of official funds (loan to the debtor countries) back to the foreign commercial banks that made the loans in the first place. Four different types of events were tested.

From October 1982 to February 1983, the IMF made loan commitments to Argentina, Mexico, Chile, and Brazil, The main result is that the stock market did not change significantly in light of the IMF loan commitments, as market investors anticipated larger commitments to the indebted neighboring countries after the commitment to Argentina was made.[7] And even in Argentina's case, only two banks enjoyed significantly positive returns over the 3-day event period.

The hypotheses for zero coefficients are rejected for the exposed banks and for all banks together, as expected.

But they also were rejected at the 10% level for nonexposed banks. This points to possible contagion. However, the hypothesis that the event parameters are equal is rejected for all three groups of banks, indicating that investors knew at least some information about each individual bank's exposure level. This, on the contrary, implies the rational pricing hypothesis. In general, the test results are not always consistent with each other and few significant results are obtained. The obscure results may be attributed to mismatching the data selection with the event periods. All three groups of banks are categorized by using the exposure data till the end of 1988. The tests could be very misleading when the actual data used were dated several years later. Also, the study left unexplained how market investors knew information about individual bank's exposures without getting it as public information.

The IMF's direct resolution of the Asian crisis in 1997 consists of clustering events that can be analyzed by conducting multivariate analyses. The IMF's bailout of South Korea in December 1997 is considered as an event that simultaneously affected all firms related cross-sectionally. The IMF's direct involvement in the global financial crisis from mid-1997 to early 1999 spurred a great deal of discussion among political leaders and economists worldwide as to whether the policies of (actions by) the IMF were appropriate to solve the crisis, and whether the existence of the institution itself was necessary at all.

Zhang (2001) examines whether the IMF bailout of South Korea in early December 1997 produced significantly positive abnormal returns in the equity values of the lending institutions. If significant positive abnormal returns occurred, then we can infer that IMF bailouts are probably generating "extra" positive wealth for the private shareholders, since potential losses without the bailouts are assumed to have negative impact on the equity values of creditors.

Zhang also examines the contagion pricing notion versus the rational pricing notion. More specifically, it is to examine whether equity prices of banks with similar foreign exposure features respond to their foreign exposure levels equally cross sectionally. If so, then equity prices change with exposure levels proportionally, which indicates the existence of rational pricing in international debt markets.

The abnormal returns of the individual banks are aggregated cross sectionally into the three portfolios based on the three bank subgroups in the study: the South Korean exposed bank group, the foreign but non-South Korean exposed bank group, and the pure domestic lending bank group. Because of the clustering of the event announcements, multivariate analysis is employed to adjust for the variance estimation to take into consideration the cross-sectional correlation between the banks in each portfolio and between portfolios. Significantly positive abnormal returns are found for the three different bank groups on the event dates, except in one case.

The event impacts on the different bank groups are different. The South Korean exposed bank group

experienced the largest positive gains among the three groups, while the foreign but non-South Korean exposed bank group did not outperform the pure domestic lending bank group. This latter result may be attributed to the fact that the lack of unison of the geographical distribution of the foreign exposure among this group of banks renders the direct comparison of their respective foreign exposures less meaningful. For banks that had no or an insignificant amount of emerging market exposure, their equity behavior may be closer to that of domestic banks than to the South Korean exposed banks.

The empirical evidence here clears the controversy regarding whether the IMF generated a wealth transfer in its bailout of South Korea in late 1997. The focus of the future discussion is not whether the IMF has generated a wealth transfer from the public funds to the private shareholders, but whether this could be avoided and how?

Zhang and Karim (2004) test the informational efficiency of financial markets related to the IMF bailout of South Korea. Informational efficiency is defined as how fast the news of the bailout announcements is incorporated into the equity pricing of U.S. banks that lend in the international debt markets. If the news of the bailout announcements were incorporated into equity prices immediately, then the abnormal returns of the foreign exposed banks would be significant on event dates but insignificant on nonevent dates. Because the IMF bailout happened in international debt markets, foreign exposed banks were directly involved, and the foreign exposure variable should be directly related to their return changes. Thus, the existence of informational efficiency can be inferred by observing whether the coefficient estimate of the foreign exposure variable is significant in terms of equity pricing on both the event and nonevent days. It has been shown in the literature that the foreign exposure variable has been the most important variable in studying equity responses in international debt crises. Presumably, if the market is informationally efficient, then the foreign exposure variable should be incorporated into the equity pricing, and its coefficient estimate is significant on the event dates, but the variable should not be incorporated into the equity pricing, and its coefficient estimate is insignificant on the nonevent dates.

For the foreign exposed banks, the mean abnormal returns tend to be significant on event dates but insignificant on nonevent dates. This evidence indicates that the news of bailout announcements was incorporated into the equity pricing immediately. There was no delay or lag effect reflected in the foreign exposed banks' equity prices. This supports the existence of market informational efficiency during the IMF bailout of South Korea in late 1997. Also, a quadratic cross-sectional regression model is employed to further examine this question by studying whether the equity returns changed proportional to the exposure levels. The

CAR model on the main event date and the cumulative regression of ARs on both event dates are significant at the 5% level, while the CAR models on nonevent dates are not significant. The evidence indicates that the market is informationally efficient during the IMF bailout of South Korea in late 1997 as investors incorporated the foreign exposure into pricing their bank equities rapidly and proportionally. There is a significant positive relationship between the banks' equity prices and their respective exposure levels on the event days. This relationship is not shown on the nonevent dates. The empirical evidence here indicates that the banks' foreign exposure information seems to be either publicly available to the markets, or investors are able to get access to this type of information.

51.3 Suggestions for Future Research

Existing literature has tried to answer the question of whether there is a potential wealth transfer from the IMF to the private shareholders of international bank creditors resulting from IMF bailouts. A more pertinent question, which is also the central debate of all the bailout events, is left unanswered. This is the issue of a potential moral hazard problem in international financial markets. The test of moral hazard requires the testing of structural risk changes before and after a bailout event. The existence of the moral hazard problem is indicated if the risk structure changes that occur after the event are significant.

While the foreign exposure variable is probably the most important variable in this type of study, the exposure data for a specific country are not available all the time. Also, due to the lack of data reporting unison, the foreign exposure examined in the literature cannot be specified according to detailed geographical locations either. The test results would certainly be improved if such data were to become available in the future.

The results would be more complete if other international lenders could be examined simultaneously along with U.S. bank creditors.

On the methodology side, while it is common to use a two-index market model in bank studies to provide the parameter estimates, which are used in the event window to calculate the abnormal returns, the significance of the contribution and the depth of the effect of the second index (usually a stationary interest rate index), in addition to the market index, needs further exploration. In other words, whether the results are sensitive to the omission of the second index or to an alternative interest rate index deserves more research effort. Also, autocorrelation is often assumed to be zero in the literature. The complexity of incorporating autocorrelation into the models so far has prevented this type

of analysis being carried out in event studies. While this may not cause serious problems, the incorporation of autocorrelation into the variance estimation should give more accurate results and inferences.

Further, a random coefficient model can be employed in the estimation window to allow for any possible structural changes before the underlying event window. If multiple coefficients are obtained, then the most recent one should be used in the event window analysis. This step is especially necessary when the length of the estimation window is long.

Notes

1. See the IMF's Articles of Agreement online at: http://www.imf.org/external/pubs/ft/aa/index.htm.
2. Radical differences also exist as to whether the Asian countries' markets have been opening enough or whether the countries should strengthen the free-market aspects of their economies before they open further. Related discussions also focus on the transparency and regulation issues in those troubled countries (Camdessus, January 16, 1998a).
3. For example, Summers (1998) said that: "The IMF has a unique ability to provide apolitical, conditional finance… in the context of strong reforms."
4. Camdessu's (January 22, 1998b) address at Transparency International: "The IMF helps members impose the management of their public resources and establish a stable and transparent regulatory environment for private sector activity, a *sine qua non* for economic efficiency and the eradication of corruption."
5. Same as endnote 1.
6. The influential *Dong-A Ilbo* newspaper claims: "The party is over, Korea's international standing has shamefully crashed," extracted from "Out of Our Hands," Lee, 1997, *Far Eastern Economic Review*, p. 81.
7. Another explanation would be that banks were not required to publish their developing country exposures at that time. This made it much more difficult for the investors to respond in any meaningful way.

Corporate Governance: Structure and Consequences

Bikki Jaggi

Abstract

We discuss in this chapter important aspects of the corporate governance structure and examine its impact on corporate performance. We especially focus on internal and external control mechanism and discuss how they make corporate governance more effective, enhance the quality of financial reporting, improve the firm's performance, and thus enhance firm value.

With passage of the Sarbanes-Oxley Act in 2002 (SOX), two important changes have taken placed in the internal control mechanism. First, the audit committee has received increased attention; it has been given authority to appoint external auditors and to deal with them directly on accounting issues. Moreover, it has the responsibility to ensure high quality of financial reporting. Second, internal controls have been strengthened to provide an effective monitoring of managerial activities. The main objective of internal controls is to ensure that managerial activities are properly supervised and managers do not use the flexibility provided in the accounting standards to achieve their own goals that are inconsistent with investors' goals. In order to enhance the quality of financial reporting, managers are especially monitored to ensure that they do not engage in policies and activities that result in manipulation of reported earnings.

The SOX has also improved the external control mechanism, provided by external auditors and market controls. The SOX especially focuses on ensuring independence of external auditors by restricting their functions to auditing only and not permitting them to perform advisory and other forms of non-auditing services, with the exception of tax services, so that their independence is not compromised. Additionally, the auditor in-charge is rotated under SOX to ensure his/her independence. We also discuss different anti-takeover control devices, which are triggered when a firm becomes a target for takeover because other firms perceive the target's weak performance as an opportunity for takeover and benefit from it.

52.1 Introduction and Framework for This Chapter

In this chapter, we discuss important aspects of the corporate governance structure and also discuss the rules and regulations, especially introduced by the Sarbanes-Oxley Act 2002, to improve the effectiveness of corporate governance. In Section 52.2, we explain what is meant by corporate governance and discuss its importance in the public companies. Additionally, in this section, we discuss certain aspects of Sarbanes-Oxley Act 2002 which focus on improving corporate governance of the US companies. Important characteristics of corporate structure are discussed in Section 52.3. In Section 52.4, we examine how the corporate governance functions in the US companies and we focus on the role of different committees in making it effective. In Section 52.5, we explain the need for internal control and focus on the requirements under the Sarbanes-Oxley Act 2002. The use of market control mechanism for smooth functioning of corporate governance is examined in Section 52.6, and the effects of corporate governance on firm performance and financial reporting are briefly discussed in Section 52.7.

52.2 Definition and Importance of Corporate Governance

52.2.1 What Is Meant by Corporate Governance?

Corporate governance has been defined from different perspectives in the literature as well as in practice, and these approaches potentially cover a variety of distinct economic phenomena. Schleifer and Vishny (1997) define it from the investors' perspective and describe it as a mechanism in which the capital suppliers assure themselves of getting a return on their investments in corporations.[1] The Office of Economic and Corporate Development (OECD) (1999) describes corporate governance as a system by which business corporations are directed and controlled. This concept of corporate governance includes a corporate governance framework that specifies distribution of rights and responsibilities among different participants in the corporation and a corporate structure that includes the Board, Managers, Shareholders, and other Stakeholders. Additionally, the structure spells out the rules and procedures for making decisions on corporate affairs. Some authors, however, consider corporate governance as a tool that is used to promote corporate

fairness, transparency and accountability (e.g. Wofensohn, ex-President of World Bank). Mathiesen (2002) describes it is as a mechanism that investigates how to secure and motivate management by using the incentive system, including contracts, organization designs, legislation, etc.

In order to have a better understanding of corporate governance, we first briefly define the concept of Corporation. Overall, a Corporation is described as an instrument through which capital is assembled for the activities of producing and distributing goods and services and making investments. In other words, it is a mechanism that allows different parties to contribute capital, expertise, and labor, for the benefit of all. This concept of Corporation creates a limited liability for investors, and it separates the corporation from its owners, managers and employees. The limited liability leads to a limited authority for shareholders, which primarily includes the right to elect directors. The directors have the fiduciary responsibility and the management runs the corporation to increase the shareholders' wealth and protect their interests.

Based on the above description of a corporation, we define corporate governance in a broader term as follows: The corporate governance is a mechanism for directing and controlling the corporation, and it includes a governance structure that specifies the distribution of rights and responsibilities of different components of the structure, which consists of the Shareholders, the Board, and the Managers. It provides rules and procedures for making managerial decisions on corporate affairs and on the monitoring mechanism over managerial decisions and activities.

52.2.2 Agency Problem and Corporate Governance

The separation between capital providers and managers gives rise to an **agency problem** in corporations. The agency problem arises because of the conflict of interests among different groups of people working in the corporation, which include the shareholders, the managers, the employees, and the outside parties dealing with corporation, such as, suppliers, creditors, clients, etc. The conflict may be between the stockholders and management, the stockholders and bondholders, and between the majority stockholders and minority stockholders. As a result of this conflict, different groups may not be able to work cohesively to achieve the company's goals. Instead, they may focus on their group's goals at the cost of other groups. Consequently, the agency conflict is not conducive to enhancing the shareholder value in a corporation. Thus, one of the objectives of corporate governance is to minimize the effect of agency conflict on corporate performance so that the company's goal to maximize the shareholders' value is achieved.

---

[1] Refer to Schleifer and Vishny (1997) for a survey on corporate governance.

52.2.3 Need and Importance of Corporate Governance

Corporate frauds, bankruptcies and other financial catastrophes in 1990s that led to destruction of shareholders' wealth in billions of dollar, loss of jobs, criminal investigation of executives, bankruptcies, etc. generated renewed interest of politicians, regulatory agencies and academics in corporate governance. Typical examples of large corporate failures include Enron, Worldcom, Global Crossing, Bear Stern, Tyco, Adelphia, etc. Among other things, corporate failures highlighted the weaknesses in corporate governance that enabled managers to maximize their own wealth by ignoring the public companies' overall goals of protecting shareholders' interests and maximizing company value. Additionally, the impact of corporate failures on the stock market and country's economy became quite evident and it was realized that weak corporate governance could become hindrance in the smooth functioning of the stock market and it could also jeopardize economic growth in the country.

Recognizing the importance of corporate governance, especially for gaining investor confidence for proper functioning of the stock market, the political leadership, policy makers and regulators decided to develop certain ground rules for smooth functioning of US companies. Their efforts culminated in the passage of the Sarbanes-Oxley Act in 2002.

52.2.4 Impact of Sarbanes-Oxley Act 2002 (SOX) on Corporate Governance

The main objective of SOX is to provide rules and regulations for proper functioning of public companies and to regulate the activities of professionals associated with these companies, which include the financial intermediaries, insurance companies, brokerage houses, accounting and auditing professionals, etc. Moreover, the Act provides control mechanism to improve the corporations' monitoring function to assure the investment community that managerial decision and activities are properly supervised. This Act in fact is the most important legislation after passage of the Securities and Exchange Acts in 1933 and 1934, which for the first time provided rules and regulations to legislate corporate financial activities in the United States.

New rules and regulations contained in the Act for monitoring managerial activities and decisions are designed to ensure that managers do not focus on the short-term goals which might help them to maximize their own compensation, including bonus, and thus enhance their own wealth. The rules are intended to discourage them to engage in earnings manipulation, overstatements, enhanced risk taking, providing misleading information to investors, and an outright fraud. The new control mechanism contained in this Act is designed to provide reliable and up-to-date information on corporate performance to investors on a timely basis. It requires the development of rules and regulations for generation of financial distress information that becomes available to investors well ahead of time so that the shareholders do not have to wait for this information until it is too late and the impact of financial distress is already having its effect on the company's stock price.

52.3 Important Elements of Corporate Governance

52.3.1 Corporate Governance Structure

There are two types of corporate governance structures and these are known as the Unitary Corporate Board and Two-tier Corporate Board.

52.3.1.1 Unitary Corporate Governance Structure

The Unitary Corporate Board consists of only one Board of Directors and this board is created to look after the shareholders' interests in the company. The company management headed by the Chief Executive Officer runs the day-to-day affairs of the company, and the Board of Directors provides the monitoring and advisory functions. This type of corporate system is mostly used by companies in the common law countries, and especially in the US and the UK.

Functions of the Corporate Board in this system generally are the following: (1) to fulfill the legal requirements of the corporate charter, (2) to protect shareholders' interests, (3) to counsel and advise management, (4) to review and approve corporate plans and actions, (5) to monitor management activities, (6) to assess management performance, (7) to decide on management compensation, (8) to decide on hiring and firing of top management, and (9) to serve as a link between external auditors and management.

Members of the corporate boards in this system are elected by the stockholders in the annual meeting. The slate for election is, however, prepared by the nominating committee of the existing Board of Directors, and their decision to formulate this slate is significantly influenced by the CEO's recommendations.

52.3.1.2 Two-Tier Corporate Governance Structure

The Two-tier Corporate Structure also known as the Dual corporate system consists of two boards, which are known as the Management Board and the Supervisory Board (Vorstand

and Aufsichtrat respectively in German language). The Management Board is responsible for day-to-day operations of the company, whereas the Supervisory Board takes care of all capital providers' interests instead of focusing on the shareholders' interests, and capital providers include banks, financial institutions, investment companies, other corporations, etc. In view of different focus of this board, appointment of its members need not be based on their impartiality and independence. Instead their appointment is based on their capability to represent the interests of a particular group of capital providers. Thus, their appointment generally reflects the company's financial and commercial relationships.

In addition to the capital providers, the German Supervisor Board also includes a representative of employees so that the employees also have a voice in the Board. The Two-tier Corporate Board System is generally used by the companies in the German speaking countries.

52.3.2 Two-Tier Corporate Structure in the Chinese Firms

The Chinese public companies also follow the Two-tier Corporate Board System, but it differs from the German Two-tier system. Though supervisors in the Chinese firms are appointed by the controlling shareholders, their appointment is generally done by the Chinese government in most companies because the government holds the controlling interest in these companies. It has been observed that the appointment of supervisors is generally done on their political affiliations and contributions. Supervisors in the Chinese companies can be either insiders or outsiders.

A significant difference in the two-tier system in the Chinese companies compared to the German companies is the authority of the Supervisory Board to appoint members of the Management Board. Whereas the German Supervisory Board has the authority to appoint or dismiss the members of the Management Board, the Chinese Supervisory Board has no authority to appoint or dismiss these members. The Chinese Management Board is also appointed by the Chinese government, which is the majority shareholder in most of the companies.

52.3.3 Independence of Corporate Boards

52.3.3.1 Different Types of Directors
The corporate board directors can be classified into the following three categories: insiders (executive directors), outsiders (non-executive independent directors), and grey (directors with some interest in the firms, such as bankers, attorneys, etc.). An important question in this regard is how

important it is to have an independent corporate board in the Unitary Corporate Structure? In other words, should a majority of these directors be independent outside directors.

52.3.3.2 Corporate Failures and Corporate Board Independence
The board independence started attracting increased attention only recently after failures of large US corporations. It is argued that an important reason for corporate failures has been the lack of corporate board independence, which resulted in inadequate monitoring of managerial decisions and activities. In most cases, the CEO conducted the company affairs and the board did not provide effective monitoring of managerial decisions and activities. In fact, the corporate board in most cases has been quite passive and existed in form only, and the board members never questioned the managerial decisions. Apparently, the board members in most cases were appointed based on their personal relations with the CEO or based on their interest in the company in some form, which impaired their independence and took away the incentive to question the managerial decisions. Thus, the main force behind their appointment probably has been their loyalty to the appointing authority.

52.3.3.3 Positive Aspects of Corporate Board Independence
It is now commonly recognized that independence is an important factor for the board to be effective. In fact, it is argued that a majority membership of the board should be independent of the CEO, meaning that a majority of board members should be non-executive independent outside directors. Some important arguments supporting the appointment of independent directors are as follows: First, it is argued that independent outside directors are expected to be more effective in monitoring managerial decisions and activities because they will be free of managerial influence, especially the CEO. Second, these directors will be in a better position to provide advice and guidance to the management based on their experience at other firms, and their expertise and experience gained at other companies will prove to be beneficial to the firm. Third, monitoring of managerial decisions and activities by independent board members is likely to improve the quality of financial disclosures. As a result of effective monitoring, managers will refrain from manipulating reported earnings to meet their desired goals, and consequently it will improve the quality of reported information. Fourth, independence of corporate board members will add to the credibility of financial information disclosed by firms, especially earnings announcements. Fifth, effective advice and guidance from independent board members with extensive experience in other firms will enable managers to improve the firm's operating performance. Sixth, better operating performance is likely to result

in better market performance for the firm and this will enhance firm value.

52.3.3.4 Negative Aspects of Corporate Board Independence

Several empirical studies have evaluated whether independent boards will result in better operating and market performance for the firms. These studies, however, provide mixed findings. The lack of empirical evidence supporting the effectiveness of independent corporate boards is probably because of the weaknesses associated with board independence. First, it is argued that the board's effectiveness depends on the reliability of information on which the board makes the decisions. In the absence of executive directors, there is likely to be a higher information asymmetry. The availability of information to the board is likely to be limited. In fact, there will be lack of inside information.

Second, motivation of independent directors to provide effective monitoring and advice is questionable because outsiders are likely to lack motivation to devote time and energy to understand the problems and issues facing the company and find solutions to these issues and problems. Moreover, there is no legal responsibility for outside directors for providing effective monitoring and advice.

Third, their busy schedule may also add to the lack of their motivation to solve the company's problem. It is argued that in addition to taking care of their own company, outside directors serving on several other boards will have very busy schedule, which will have a negative impact on their performance as a director of other companies.

Fourth, their independence may be questionable because their appointment will depend on their relations with the CEO of the firm. Their appointment based on their friendship with the CEO of the firm or based on their obligation to the firm because the firm's CEO serves as a director on their company, will weaken their independence and effectiveness.

52.3.3.5 Ownership Structure and Corporate Board Independence

Independence of outside directors is also likely to depend on the ownership structure of the firm. The majority ownership of the firm can either be in the hands of the controlling shareholders or it can be widely dispersed and there are no controlling shareholders. The first type of firms is known as family-owned and controlled firms. The agency problem differs between the two types of firms. In the family firm, the agency conflict is between the controlling and non-controlling shareholders, whereas the agency problem in the widely dispersed ownership firm is between shareholders and managers.

Independent directors in the family firms are appointed by the controlling shareholders and their loyalty is likely to be with the appointing shareholders and they are not likely to focus on the interest of the minority shareholders. This will result in an ineffective monitoring by an independent board. This situation is likely to provide greater opportunities to the controlling shareholders to usurp formal powers and transfer wealth from the minority shareholders to the majority shareholders. In other words, there will be a greater opportunity for the majority shareholders for opportunistic behavior to enrich themselves at the cost of the minority shareholders.

52.3.3.6 Executive Directors' Need on the Corporate Boards

In order to complete the discussion on corporate board independence, we would like to point out the advantages of the Executive Directors on the corporate boards. Among other factors, the Executive Directors are more knowledgeable in the company affairs, they have better inside information, and they have no time constraint to devote to the company affairs. These advantages suggest that a completely independent corporate board will not be desirable. The presence of Executive Directors on the board will improve the Board's effectiveness.

52.3.4 CEO Duality and Corporate Board Independence

The CEO duality is also considered to be an important aspect of corporate board independence. This aspect of independence deals with the Chairman of the Corporate Board. The Chairman of the Corporate Board can either be the Chief Executive Officer (CEO) or he/she can be an outsider independent director. If both positions of the Chairman of the Corporate Board and CEO are held by a single individual, i.e. when CEO is also the chairman of the corporate board, the situation is termed as CEO duality. An important question facing regulators, corporations, investors and academics is whether CEO duality is good for corporations. Is it good for the monitoring mechanism and will it improve corporate performance? Historically, the CEO duality has been a common practice in the corporate world. An entrepreneur who starts the corporation generally holds both positions in the beginning, and this situation does not create any concern for investors. When corporations become large and ownership gets widely diffused, the CEO duality is considered undesirable because it can weaken the monitoring mechanism or it may not be good for corporate performance. We briefly discuss both positives and negatives of CEO duality.

52.3.4.1 Positive Aspects of CEO-Duality

There are several positive aspects of CEO Duality, which make it desirable under certain circumstances. First, when the positions of chairman of corporate boards and CEO are held by a single individual, there is a lower conflict and the

individual is able to devote his/her full energies to the job and there are less diversions resulting from the conflict between the chairman and CEO. Consequently, we can expect an improvement in the corporate performance and also in the board effectiveness. Second, the CEO is not concerned about any antagonism from the corporate board and especially from the board chairman. Thus, this situation is likely to result in a better working environment which will be conducive to the operating and market performance of the firm. It is generally observed that the CEO duality performs a useful function in small firms and also in the firms where ownership is concentrated in a few hands.

52.3.4.2 Negative Aspects of CEO-Duality

As the corporations become large and there is no concentration of ownership, monitoring of managerial activities becomes more important. In order to provide effective monitoring over managerial decisions and activities and to ensure that management are working in the best interest of shareholders, it is important for corporate boards, especially the board chairman, to be independent of the CEO. It is argued that in the case of large corporations, CEO duality is not likely to be conducive to ensure the shareholders' interests. Instead, the CEO duality is likely to empower the CEO to make decisions which may not be in the best interest of shareholders and instead the managers will be more concerned to enhance their own interests and personal wealth. In order to ensure that management is not working against the shareholders' interest, an effective monitoring mechanism will be needed and one important aspect of this mechanism will be an independent corporate board, headed by an independent chairman. Furthermore, the CEO duality is likely to aggravate the agency problem.

52.3.4.3 CEO Duality and Institutional Shareholders

The institutional investors, especially CALPERS (California Public Employee Pension Fund), are especially against CEO duality because they are concerned that CEO duality would impair board independence which will not be conducive to enhance the shareholders' value. Some corporations agree with CALPERS and have given the responsibilities of the board chairman and Chief Operating Officer to two separate individuals, whereas other corporations believe that CEO duality is in the best interest of the firm because it results in better performance. The latest trend is, however, toward splitting the responsibilities of the board chairman and CEO.

52.3.5 Specialization of Independent Directors

Will specialization of independent directors on the corporate boards improve the board's effectiveness? Examples of specialization of independent directors are bankers, attorneys, accountants, academics, etc. The Sarbanes-Oxley Act requires that at least one audit committee member be a financial specialist. This means that at least one independent director should be a specialist. A question arises whether independent directors with specialization improve the effectiveness of the corporate boards. It can be argued that some specializations will be beneficial in improving the board's effectiveness. For example, a banker on the board will enable the board to provide an effective advice on dealing with banks on financing and other financial transactions, and he/she will also provide an effective monitoring function. Similarly, legal specialization will be beneficial with regard to the legal affairs of the company. Agrawal and Chadha (2005) provide evidence that a financial expert in an audit committee is likely to limit the likelihood of restatements.

52.3.6 Appointment of Directors: Investors' Activism in Nominating Them

Directors in the unitary corporate governance system are elected by the shareholders in the annual meeting. The existing board of directors prepares a slate for election of directors and this slate is sent to the shareholders in the proxy statement. The slate is prepared on the basis of nominations of directors by the existing board or by the Chief Executive Officer. The shareholders also have the option to nominate directors, but the Board is under no obligation to include nominations from the shareholders on the slate for election of directors.

The nominated directors are elected by shareholders by a simple majority. The shareholders have the right to vote for or against the nominated director. If he/she director fails to obtain a simple majority, he/she is not elected. The existing board has the right to re-nominate the defeated director for re-election.

This process of nomination has been criticized by the activists because it does not give any right to investors to nominate a director unless the existing board approves it. This issue has been debated for a long time. After a careful consideration of the issue, the SEC issued a new rule in 2010 that investors with 5% shareholdings have the right to nominate a director on the board (with or without the approval of the existing board). This rule was challenged in the court by the US Chamber of Commerce and Business Roundtable; they charged that the rule was arbitrary and capricious, violated the Administrative Procedure Act and the SEC failed to properly assess the rule's effect on "efficiency, competition and capital formation" as required by law. The US Court of Appeals for the District of Columbia Circuit rule in 2011 that the SEC rule was issued without an appropriate cost-benefit analysis of the rule. The court asked the

SEC to reconsider this issue and evaluate costs and benefits involved in allowing investors to nominate directors.

52.3.7 Corporate Board Size

One of the important characteristics of a corporate board is the board size. What is an optimal size of a corporate board? This issue has been extensively discussed in the literature and practice, and there is no consensus on this issue. Most of the discussion on this issue has been focused on whether a small or a large board is more effective. It is generally argued that the board should be small enough to conduct the business effectively, yet it should be large enough so that different individuals can be assigned to different committees and different viewpoints can be presented in the board.

52.3.7.1 Large Versus Small Corporate Boards

It is argued that a large board has more capabilities for problem solving and it allows individuals to be more effective in their committee assignments because they are not likely to be over-burdened with such assignments. Jensen (1993) on the other hand, argues that keeping the board small will help in improving the firm performance, and he is of the opinion that if a board gets beyond seven or eight members, it is less likely to function effectively and this situation would make it easier for the CEO to control the board. Lipton and Lorsh (1992), further argue the norms of behavior in large boards can become dysfunctional, and that the large boards lack group cohesiveness.

52.3.7.2 Corporate Board Size and Firm Performance

Hermalin and Weisbach (2003) provide empirical evidence that the board size is negatively related to both firm performance and the quality of decision making. Similarly, Yermack's (1996) findings also show a negative relationship between the firms' market valuation and board size. Eisenberg et al. (1998) document an inverse relation between the board size and profitability for small and midsize companies in Finland. Carline et al. (2002) provide similar evidence for the UK firms. But, Van Ees et al. (2003) find no evidence on the relationship between the board size and firm performance in Netherlands.

52.4 Functioning of Corporate Boards

In this section, we discuss how the US corporate boards work in actual practice, and we cover the topics of committee structure, meeting frequency, busy boards, and gender participation.

52.4.1 The Committee Structure

In order to be effective, corporate boards function through several committees. Some of these committees are permanent committees, while others are ad-hoc committees. The corporate boards are required to have at least the following three permanent committees: audit committee, compensation committee, and nomination committee. We discuss the important aspects of these three committees.

52.4.2 Audit Committee

Prior to SOX, it was optional for firms to establish an audit committee in the firm. The main function of the audit committee prior to SOX was to serve as a link between the CEO and external auditors. The committee primarily provided advice to the management and assisted the management in resolving the differences between auditors and management. The nature of audit committee has drastically changed with the passage of SOX. It is now mandatory to have an audit committee and SOX has mandated certain functions and responsibilities of this committee, and the SEC provides the rules to improve disclosures related to this committee. The NYSE and NASDAC sponsored the Blue Ribbon Committee in response to an increasing sense of urgency surrounding the need for responsible financial reporting. Based on the recommendations of this committee, the stock exchanges now also require the establishment of an audit committee by all registered US companies.

Under the revised rules, the audit committee's primary function is to oversee the firm's financial reporting process, and to prevent fraudulent accounting statements. Thus, the audit committee plays a critical role in financial reporting by overseeing and monitoring the management's decisions and activities and by supervising independent auditors' participation in the financial reporting process. The audit committee is also entrusted with the responsibility of resolving differences between outside auditors and management with regard to application of the Generally Accepted Accounting Principles. In order to do so, the committee is required to meet regularly with the firm's outside auditors and internal financial managers to review the corporation's financial statements, audit process, and internal accounting controls.

It is argued that the new dynamics of the capital markets have presented the companies with an increasingly complex set of challenges. An important challenge is that the companies are under increasing pressure to meet the earnings expectations. Regulators and investors have become increasingly concerned about inappropriate "earnings management", the practice of distorting the true financial performance of the company. The changes in the market

and the increasing pressures on companies to maintain positive earnings trends have highlighted the importance of strong and effective audit committees. Thus, the audit committee now plays a critical role in the financial reporting system by overseeing and monitoring the management, and also by supervising independent auditors' participation in the financial reporting process.

52.4.2.1 Establishment of an Audit Committee

We highlight the rules and regulations for the establishment of audit committees and their functions and composition, and also discuss whether specialization of the audit committee member will improve the committee's effectiveness. We also briefly discuss the role of the audit committee in maintaining the complaint channels in the firm.

The term "audit committee" is defined as a committee (or equivalent body) established by and amongst the board of directors of an issuer for the purpose of overseeing the accounting and financial reporting processes of the issuer and audits of the financial statements of the issuer (SOX). If no such committee is established, the entire board of directors serves as the audit committee.

52.4.2.2 Functions of an Audit Committee

The audit committee is responsible for the appointment, compensation, and oversight of the work of any registered public accounting firm employed by the firm. The registered public accounting firm shall report directly to the audit committee, and it will have to resolve disagreements between management and the auditor on financial issues and reporting.

The audit committee is required to pre-approve all auditing services to be provided by an external auditor. These services may entail providing comfort letters in connection with securities underwritings or statutory audits required for insurance companies for the purposes of State law and also non-audit services to be provided by the auditor of the issuer. It is also required to pre-approve all non-audit services, including tax services, if they are not specifically prohibited to be performed by an auditor of the issuer.

52.4.2.3 Waiver of Pre-approval of Non-audit Services

The pre-approval requirement is waived with respect to the provision of non-audit services for an issuer, if the aggregate amount of all such non-audit services provided to the firm constitutes not more than 5% of the total amount of revenues paid by the firm to its auditor during the fiscal year in which the non-audit services are provided, or such services were not recognized by the firm at the time of the engagement to be non-audit services. The performance of such services is promptly brought to the attention of the audit committee of the firm and approved prior to the completion of the audit by the audit committee or by one or more members of the audit committee who are members of the board of directors to whom authority to grant such approvals has been delegated by the audit committee.

The audit committee may delegate to one or more designated members of the audit committee who are independent directors of the board of directors, the authority to grant pre-approvals. The decision of any member to whom authority is delegated shall be presented to the full audit committee at each of its scheduled meetings. The registered public accounting firm that performs audit for the firm is required to report to the audit committee all critical accounting policies and practices used, all alternative treatments of financial information within generally accepted accounting principles that have been discussed with management, ramifications of the use of such alternative disclosures and treatments, and the treatment preferred by the registered public accounting firm. Moreover, the public accounting firm is also required to report any other material written communications between the registered public accounting firm and the management of the issuer, such as any management letter or schedule of unadjusted differences.

52.4.2.4 Independence of an Audit Committee

The SOX requires that each member of the audit committee of the issuer shall be a member of the board of directors of the issuer, and shall otherwise be independent. In order to be considered to be independent, a member of an audit committee may not, other than in his/her capacity as a member of the audit committee, the board of directors, or any other board committee in the firm, accept any consulting, advisory, or other compensatory fee from the firm. Moreover, the audit committee shall not be affiliated in any way with the firm or any of its subsidiaries.

The SEC is, however, authorized to exempt a particular relationship with respect to audit committee members, as it determines appropriate in light of the circumstances. This exception implies that all members of the audit committee may not be independent.

Under the revised listing standards of the NYSE, AMEX, and NASD, under exceptional and limited circumstances, companies may appoint to their audit committee one director who is not independent if the Board determines that membership on the committee by the individual is required by the best interests of the corporation and its shareholders, and the Board disclose, in the next annual proxy statement subsequent to such determination, the nature of the relationship and the reasons for that determination.

Small companies are, however, exempt from disclosing reasons for non-independence of a committee member. All companies are, however, required to disclose whether audit committee members are independent or not.

52.4.2.5 Financial Expertise in an Audit Committee

The SOX requires that at least one member of the committee shall be financial expert. Furthermore, it requires that the issuer should disclose whether or not, and if not, the reasons for not having at least one member who is a financial expert. The term "financial expert" is defined through education and experience as a public accountant or auditor or a principal financial officer, comptroller, or principal accounting officer of the firm. The individual shall come from a position involving the performance of the function that shows an understanding of generally accepted accounting principles and financial statements, and experience in the preparation of auditing of financial statements of generally comparable firms, and the application of such principles in connection with the accounting for estimates, accruals, and reserves or experience with internal accounting controls. The individual should an understanding of the audit committee functions.

52.4.2.6 Disclosures on Audit Committee

The SEC adopted new rules and amendments to its current rules to require that companies include in their proxy statements certain disclosures about their audit committees and reports from their audit committees. The firms are required to inform the shareholders of the audit committee's oversight with respect to financial reporting and underscore the importance of that role in the proxy statement. This disclosure should include that (1) the audit committee has reviewed and discussed the audited financial statements with management, (2) the audit committee has discussed with the independent auditors the matters required to be discussed by SAS 61, as may be modified or supplemented, and The audit committee has received the written disclosures and the letter from the independent auditors required by ISB Standard No. 1, as may be modified or supplemented, and has discussed with the auditors the auditors' independence. The companies must disclose in their proxy statements whether their audit committee is governed by a charter, and if so, include a copy of *the charter as an appendix to the proxy statement at least once every 3 years. This should help investors to understand the role and responsibilities of the audit committee.*

52.4.3 Nominating/Governance Committee

The purpose of the Corporate Governance/Nominating Committee is to assist the Board in identifying qualified individuals to become Board members, nominate directors to serve on the board and board committees. Additionally, this committee also assists the Board in assessing the Board effectiveness and it may also make recommendations to the Board for any improvements in the company's corporate governance.

52.4.3.1 Composition of a Nominating Committee

The committee generally consists of at least three directors. The chair as well members of the committee are appointed by the Board and they serve at the Board's discretion. All members of the committee are generally expected to be independent outside directors.

52.4.3.2 Responsibilities of a Nominating Committee

Authority and responsibilities of this committee are as follows: (1) to organize search for individuals who are qualified to become members of the board, (2) to retain a search firm to assist the committee in the search process for qualified candidates to become directors, (3) to evaluate the suitability of potential candidates based on the qualifications of the candidates and the board's needs based on the current board's composition, board's need for expertise, diversity, and balance between inside and outside independent directors, (4) to make recommendation to the Board on individual candidate for nomination, and (5) to keep itself abreast of trends and best practices in corporate governance, and review the company's corporate governance guidelines periodically.

52.4.3.3 Meetings and Attendance by the Company Officers

The committee is required to meet at least two times a year, or more often, if circumstances require. The committee may invite to its meetings any director or officer of the company to assist it in performing its responsibilities.

52.4.3.4 Annual Report

The committee shall conduct and present to the Board an annual performance evaluation of the committee. The committee shall review annually the adequacy of the committee's charge and recommend any changes that it deems appropriate to the Board for approval.

52.4.4 Compensation Committee

Traditionally, companies were not obligated to have compensation committees, and it was open to the board as a whole to perform the duties of the compensation committee. As a practical matter, most boards did not have compensation committees. But lately the need for this committee is being increasingly felt and laws/regulations in some states are making it a mandatory committee. Legislation or regulation in many jurisdictions requires that a compensation committee be established and maintained, and that the majority of members be independent.

52.4.4.1 Need for Expertise on Compensation Committee

While financial expertise and experience is required for an audit committee, there is no such requirement for the compensation committee. In actual practice, however, knowledge and experience in compensation and human resources issues is considered helpful for the committee to discharge its functions. Some firms also consider committee member's qualifications to recognize investor sentiment toward particular sort of compensation arrangement.

52.4.4.2 Responsibilities of a Compensation Committee

The committee's responsibilities are decided by the board and they are generally disclosed by the company so that all concerned have a better understanding of the role of compensation committee in the organization. Generally, the Board's mandate should be substantially broader than simply dealing with establishing senior management compensation levels.

The compensation committee can be assigned the following functions: (1) to establish CEO compensation, (2) to develop compensation philosophy for the company, (3) to assist with and review the compensation discussion and analysis, (4) to oversee equity compensation grant policy, (5) to assist the board in assessing and evaluating the CEO's performance, review and recommend the CEO's compensation, including salary, incentives benefits and other perquisites, (6) to recommend to the board the amount, determination and payment of remuneration t to directors, (7) to report executive compensation as required in public disclosures statements, (8) to retain and terminate outside experts to deal with compensation issues, and (9) to evaluate shareholder proposals related to executive compensation.

A tool for the committee in reviewing the structure of their company's incentive programs is risk taking by the management, and the committee should discourage programs that involve excessive risk taking.

52.4.4.3 Compensation Committee Procedures

It is important that suitable procedures are developed and implemented so that the compensation committee can function effectively and perform useful function in the organization. The corporate secretary can be helpful in formulating these procedures.

52.4.5 Frequency of Corporate Board Meetings

The number of times a board meets varies from company to company depending on the nature of business, complexity of business, role of CEO, and general policy of the companies. There is no optimal number of meetings which a board should follow. It is, however, important that the board meetings are sufficient enough to deal with important issues of the board. If the meeting frequency is low, important issues will not get the Board's attention as they deserve. In this case, the board will be making decisions without fully considering pros and cons of the issue under discussion.

52.4.6 Corporate Board Meetings and Board Effectiveness

The effectiveness of the Boards also depends on an appropriate frequency of its meetings. If the Board is not meeting when decisions need to be made, the CEO will make these decisions without the Board and this will impair the Board's effectiveness. The CEO will also not be happy if proper advice and counsel is not available when needed and this will force the CEO to make his/her decisions.

In 2002, the average S&P 500 board met 7.5 times, whereas it met 8.2 times in 2001. It is, however, reported that the frequency of the board's meeting goes down if the board committees are effective.

52.4.7 Busy Directors

Individual outside directors generally serve on the Boards of several different corporations. It has lately been observed that sometimes a director serves on four or five boards of different companies. If a director serves on more than four company Boards, he/she can be considered a busy director. An important question arises whether a busy director can be effective on any Corporate Board and whether he/she can perform a useful function on the Board and make a contribution to improve the Board's monitoring and advisory functions to enhance firm value.

52.4.7.1 Executive of One Company Serving as a Director of Another Company

The directors are generally executives of another company. In addition to their job as an executive, they have to attend the board meetings of other companies. Why a director would serve on many boards and not have enough time for his/her company? It is generally believed that these executives accept the director's position either because of personal relations with the executives of the company in which they accept the position or they accept the position to create goodwill for their company. It is conventional wisdom that directors will have less time to devote to the work of the board of any company on which he/she serves if he/she is a director on several corporate boards. If majority of directors on a Board are busy, this would mean that the Board will not

be effective. Therefore, directors should the consequences if the Board consists of several busy directors.

52.4.7.2 Limit on the Number of Directorships for a Director

Should there be a limit on the number of boards on which a director can serve? It is difficult to develop any general rule to define when a particular can be considered as a busy director and what should be the limit on the number of busy directors on a single Board. It is, however, investors' right to know about the composition of the Board and characteristics of the board members. The corporations should be encouraged to disclose information on the board composition and provide as much information on the directors as possible.

52.4.8 Diversity: Female Directors

Historically most directors have been middle-aged male directors in the companies, and only in exceptional cases directors were females or belonged to an ethnic minority community. Lately, there has been awareness that diversity in Corporate Boards is desirable because it can result in several advantages for the corporation. In more recent times, gender diversity on the Board and its workforce has become a key governance issue. Some argue that it is only equitable that the gender balance on the board is addressed and redressed given that half of the population consists of female whereas the majority of Board members in a typical Board are males.

52.4.8.1 Female Directors and Board Structure

In addition to the gender balance, it is argued that female directors are considered to bring more strength to the boardroom because of their different life experience, their way of thinking, their patience, their way of dealing with people and their cool behavior in dealing with the situation. Others argue that the main benefit of women being on the boards is the in-depth discussion in the board, which generally results in a more consensus situation.

52.4.8.2 Trend in Female Directors on Company Boards

The awareness of female directors on the Board has been noticed in several western industrialized countries. An early exponent of women's representation in the boardroom was Norway; there is an enforced quota of 40% female directors on boards of all publicly listed Norwegian companies since 2008. Spain has also introduced an equality law in 2007 requiring companies with 250+ employees to develop gender equality plans, and the legislation will become effective in 2015, which will require the Spanish companies to ensure that 40% of board members are female. The Dutch Code of Corporate Governance (2008) also advocates that the Supervisory board shall aim for a diverse composition in terms of such factors as gender and age. Similarly, the German Corporate Governance code (2009) requires the Supervisory Board to have respect for diversity when appointing the members of the Management Board. The UK Corporate Governance Code (2010) also encourages the Board to consider the benefits of diversity, including gender. This Code urges companies to have a well-balanced Board.

Diversity should, however, not be for diversity's sake. Instead, it should be for the benefit of the company, its shareholders and other stakeholders. The ultimate goal should be better monitoring and better firm performance.

52.5 Internal Controls and Corporate Boards

52.5.1 Importance of Internal Controls

Companies generally institute internal controls to provide effective monitoring over employees' activities, and these internal controls are developed to ensure that employees are following the company's policies, managerial decisions are consistent with the best interests of shareholders, corporate activities do not violate the country's laws, and that there is no collusion among managers and employees to defraud the firm. Larger corporations especially require numerous analyses and reports to assure that there is compliance with the company's policies, that protection is provided against human weaknesses, errors and irregularities, and that assurance is given to independent auditors on the accuracy of internal control system so that the scope of the audit work can be minimized. In the absence of adequate and effective internal controls, there is a danger of fraud, non-conformity with company policies, misrepresentation to managers for decision making, and misrepresentation to investors by management. These negative aspects of weak internal controls may result in financial difficulties for the firm, they may have a negative impact on the firm performance, and consequently they may have a negative impact on the stock prices, and firm value. In the severe cases of inadequacy and unreliability of internal controls, there may a danger of corporate failure.

52.5.2 Administrative Versus Accounting Controls

We generally distinguish between two types of internal controls and these are the administrative controls and accounting controls. The administrative controls consist of the firm's plan of organization, procedures, and tests

concerned with the decision making processes. The administrative controls become the starting point for accounting controls, which deal with safeguarding of assets, reliability of financial records, conformity with the accounting standards, and reasonable assurances on the accuracy and reliability of reported information. It is important that accounting internal controls are effective, and the following two conditions are the basic requirements to make these controls effective: First, there should be an effective management leadership, a good organization structure is developed, and an appropriate budgetary process is established. Second, sound accounting practices are developed in the firm.

52.5.3 Historical Perspective on Internal Controls

Historically, companies have not been required to certify whether internal controls exist in the firm and whether they are effective. But given the importance of internal controls for reliability of information to investors and danger of bankruptcy in case of inadequacy of internal controls, which may have a negative impact on smooth functioning of the financial markets and ultimately economy of the country, the policy makers and regulators could not leave it to the shareholders and managers to ensure that proper internal controls are developed in the companies. Therefore, from time to time, the policy makers and regulators had to intervene and develop rules and regulations to ensure the development of effective internal controls in the companies.

In 1977, the Foreign Corrupt Practices Act was enacted, which required the management to provide a report on the existence and reliability of internal controls in the financial statements. Despite these certifications, the weaknesses in internal control systems resulted in fraudulent reporting in several corporations and consequently there have been corporate failures. Later the Treadway Commission was established and it issued a report on the factors that led to fraudulent financial reporting and also made recommendations to deter firms to make fraudulent reporting. These recommendations especially included strengthening of internal controls to reduce the occurrence of such reporting. Following the Treadway Commission Report, the Committee of Sponsoring Organizations (COSO) was formed to develop an integrated framework of internal control.

In 1992, the COSO released guidance for designing and implementing effective internal controls, and argued that there would be potential benefits of having effective internal controls, which would include effective and efficient operations, enhanced reliability of financial reporting, and compliance with laws and regulations. There was, however, no mandatory reporting of internal control weaknesses except when there was a change in auditors.

52.5.4 Internal Controls Under Sarbanes-Oxley Act (SOX), 2002

Despite the Foreign Corrupt Practices Act and COSO regulations, weaknesses in the internal control led to several corporate failures in 1990s, which included Enron, Worldcom, Tyco, etc. The 2002 Sarbanes Oxley Act (SOX) once again emphasized the importance of internal control systems and it required all companies to institute internal controls and provide management assessment on the effectiveness of these controls. In addition, the SOX requires the large accelerated filers (firms with 750 million US dollars and above capitalization) and the accelerated filers (firms between 75 and 750 million US dollars capitalization) to provide an attestation from an external independent auditors on the managerial assessment of the internal controls' effectiveness. This Act has two important sections on internal controls and these are sections 302 and 404. We discuss the important aspects of these sections to highlight the requirements on internal controls under the current laws.

52.5.4.1 Section 302 of SOX on Internal Controls
Section 302 describes the corporate responsibility for financial reports, and requires among other things a quarterly self-assertion by the CEO/CFO, under personal liability, disclosing significant material financial information to the stakeholders and investors. The assertion should be included in the company's 10Q and 10 K, but no supporting documents or certification of independent examination is required under this section. The important aspects of this section are that the principle executive officer or the principal financial officer certifies that he/she has reviewed the report. Additionally, their statement should include that based on the knowledge of the signing officer, the report does not contain any untrue statement or there is no omission of a material fact, and that the financial statements and other financial information included in the report fairly present in all material respects the financial condition and the results of the operation of the issuing company. The signing officer is also required to state that he/she is responsible for establishing and maintaining internal controls, and he/she has designed such internal controls and has evaluated the effectiveness of these controls. Furthermore, he/she should present the conclusion about the effectiveness of internal controls and all significant deficiencies in the design or operation of internal controls.

52.5.4.2 Section 404 of SOX on Internal Controls
The section 404 deals with Enhanced Financial Disclosures and it consists of two subsections, i.e. 404(a) and 404(b). The subsection 404(a) requires that each company's annual report should include an internal control report containing the management's assessment of the effectiveness of ICFR,

whereas the subsection 404(b) requires the companies to have the auditor evaluate the effectiveness of the

There are three important reporting requirements under this section. First, the report should state that the management of the issuing company is responsible for establishing and maintaining adequate internal controls and procedures for financial reporting. Second, the report should contain management's assessment as of the end of the most recent fiscal year on the effectiveness of the company's internal controls and procedures for financial reporting. Third, it should contain a statement that the company's independent auditor has attested to and reported on the management's evaluation of the internal controls and procedures for financial reporting.

52.5.4.3 Applicability of Sections 302 and 404 of SOX

Both subsections 404a and 404b, became effective for accelerated and large accelerated filers ($75 million and above) in November 2004. Subsection 404(b) became effective in December 2007 for non-accelerated filers (less than $75 million), and they are exempted from subsection 404(b) under the D9dd-Frank Act 2010. Reporting of management self-assessment under subsection 404(a) is considered sufficient for smaller companies.

52.5.4.4 Criticism of Section 404 (b)

The main criticism of subsection 404(b), especially for non-accelerated filers, is based on the costs involved in meeting the requirements. Two surveys have been undertaken to evaluate such costs. One survey is undertaken by the Financial Executive Institute (FEI) and the other by the CPA firms. The FEI survey results report that audit fees increased 39% for the first year after SOX and average total cost was reported to be $4.36 million for the largest US companies (over five billion in revenues), and the details of the compliance costs by components is as follows: internal cost = 1.34 million; external cost = 1.72 million, and auditor fee = 1.30 million. The survey results show that all respondents believe that costs associated with compliance of section 404 exceeded the benefits.

The survey results conducted by the accounting firms D&T, E&Y and PWCoopers reported that the implementation cost for section 404 on average per company was estimated to be approximately $7.3 million, which represented 1/10th of 1% company revenues. On an average, audit fees were estimated to be approximately one-quarter of the total implementation costs per company, which means 1/40th of 1% of the company's revenues. The survey results further reported that the year-two implementation costs were expected to decrease approximately 46% compared to year-one costs, suggesting substantial non-recurring start up and

"learning curve" costs. Approximately $1.9 million or 26% of the total cost is comprised of section 404 audit-related fees. It represents about .09% of the average revenue of the total sample companies. On average, each company identified 348 deficiencies and remediated 271 deficiencies and was expected to remediate an additional 77 deficiencies.

52.5.4.5 Response to Criticism of Section 404 (b) of SOX

CalPERS (California Public Employees' Retirement System) expressed the views that the costs associated with SOX are paid by the shareholders and not by the management. It was therefore the shareholders' choice to support this cost if internal controls deliver better governance and management. It has been further argued that these costs are not significant compared to the losses suffered by investors. 55% of respondents believe that section 404 gives investors and other external users more confidence in a company's financial reports (83% respondents of large companies). In general, companies applaud the added focus on internal controls, but many respondents believe that the level of details required is impractical and bureaucratic. They argued that the support was right on, but the execution to the level of detail that was required was much more than necessary.

52.5.4.6 Auditing Standards and Internal Controls

The PACOB implemented Sarbanes Oxley Act Section 404 on internal control system by issuing Auditing Statement No. 2 on October 7, 2003. In April 2006, issued another auditing standard No. 4, which describes the steps to be used by auditors when a company voluntarily engages them to report on whether a material weakness, previously identified in the section 404 report. The main objective of this standard is to obtain reasonable assurances as to whether the previously reported material weaknesses still exist. The auditor's work is focused on whether the controls specified by management were designed and operating effectively.

52.6 External Controls and Corporate Governance

52.6.1 Two Types of External Controls

External controls over the managerial decision making process and activities are provided by external independent auditors and by the market control mechanism. We highlight a few important aspects of external controls by independent auditors, and especially discuss anti-takeover devices developed by the management.

52.6.2 External Independent Auditors

Under agency theory, external independent auditors play an important role to ensure that managers are reporting information to investors that is accurate and reliable. Moreover, independent auditors also ensure that all assets in the firm are properly accounted for and there is no misappropriation of funds by the managers to maximize their own wealth.

The Securities and Exchange Acts of 1933 and 1934 require that all companies that listed with the SEC and are publicly traded on the stock exchanges should have an independent auditor to attest to the accuracy and reliability of the financial information contained in the financial statements.

52.6.2.1 External Auditor's Functions

The SOX has clearly defined functions and responsibilities of independent auditors. The main function of the auditor is to provide attestation of the financial information provided by the management to investors, in the financial statements. The main objective is to provide reliability to the reported information. Other functions include reviewing of the client's accounting books, accounting policies and principles to ensure that accounting and principles are applied consistently, there are no inaccuracies and/or misrepresentations, and that the financial reports are comprehensive.

After reviewing the client's accounting books, auditors form their opinion with regard to the accuracy, comprehensiveness, and firm's financial difficulties which may create problems in the future. Auditors may issue one of the following opinion: clean (unqualified) opinion, qualified opinion, going concern opinion, adverse opinion, and no opinion.

52.6.2.2 Hiring of Auditors and Communication with the Firm

Under new regulations, the audit committee and not the management hires external independent auditors. External auditors also report back to the audit committee; they discuss the findings of their audit work and also their differences with the managers on accounting policies and procedures with the audit committee.

52.6.2.3 Independence of Auditors

Independence of auditors is considered important under SOX. In order to ensure independence, the SOX regulations prohibit external auditors to perform any non-audit services, except for tax services. Moreover, the regulations require rotation of the partner-in-charge of the audit so that cozy relationship the auditor and client firm is avoided. Thus, there are two important issues with regard to the impairment of independence and these are the non-audit services, and being too long on the job.

52.6.3 Market Control Mechanism

The corporate control market, which relates to takeover threats of firms that are not creating value for investors, plays an important role in monitoring managerial behavior and this has a significant impact on corporate governance. Weak performance makes these firms the targets for takeovers by corporate raiders as well as by other successful firms. These takeover threats serve as market control over managerial performance and firm performance. This market control mechanism serves as a useful function to keep the managers focused on the firm's overall goal of maximizing firm value for investors.

52.6.3.1 Anti-takeover Devices

Being aware of these threats, managers, especially entrenched managers, take necessary steps to avoid takeovers. Thus, managers along with the Board of Directors, especially when the Boards are independent, work toward building defenses to protect their companies from the threat of hostile takeovers. In order to do so, they develop anti-takeover devices, which are also known as shark repellents in the market. These devices, however, sometimes render management and the Board of Directors less accountable.

We first discuss important anti-takeover defenses, and also evaluate the role of independent boards in the development of such devices.

Green Mail
This refers to a transaction between a large shareholder and a company in which the shareholder agrees to sell his stock back to the company, usually at a premium, in exchange for a promise not to seek control of the company for a specified period. This device is used when someone buys a large stake in the company and begins to make his presence known, perhaps by making noises about trying to take over the company. The management offers to buy him out at a substantial bonus over the market price of the stock. This way the raiders achieve huge profits without even having to make a bid for the company, and managers are able to keep their jobs, and the main losers are the shareholders. The passage of this device reflects the Board's neglect of the shareholders' interests. The shareholders should be able to decide whether purchase of shares should be allowed.

Anti-greenmail measures prevent such arrangements unless the same repurchase offer is made to all shareholders or approved by a shareholder vote.

Blank Check
It refers to the authority given to the Board of Directors to issue a preferred stock. The board of directors determines the voting, dividend, conversion, and other rights for this stock.

While it can be used to enable a company to meet the changing financial needs, its most important use is to implement poison pills or to prevent takeover by placing this stock with friendly investors. This technique is thought to discourage accumulation of large blocks of stock, but the net effect on the shareholder wealth is unclear.

Supermajority

It limits the shareholders' ability to amend the governing documents of the corporation. A supermajority vote is needed to change charter/make amendments to the bylaws, total elimination of the ability of shareholders to amend the bylaws, or the ability of directors to amend the bylaws without shareholders' approval.

A Classified or Staggered Board

Directors are placed into different classes and they serve overlapping terms. Since only a part of the board can be replaced each year, an outsider who gains control of a corporation may have to wait a few years before being able to gain control of the board. This slow replacement makes a classified board a crucial component of the delay group of provisions, and one of the few provisions that clearly retains some deterrent value in modern takeover battles (Daines and Klausner, 2001). Most states, however, do not allow staggered boards after 2009.

Directors' Duties

This provision allows directors to consider constituencies other than shareholders when considering a merger. These constituencies may include, for example, employees, host communities, or suppliers. This provision provides board of directors with a legal basis for rejecting a takeover that would have been beneficial to shareholders.

Golden Parachutes

These are the severance agreements that provide cash and non-cash compensation to senior executives upon an event, such as termination, demotion, or resignation following a change in control. They do not require shareholders' approval. Such payments are generally intended to deter takeovers by increasing their costs. But these parachutes also ease the passage of mergers through contractual compensation to the managers of the target company (Lambert and Larcker, 1985).

Silver Parachutes

They are similar to Golden Parachutes in that they provide severance payments upon a change in corporate control, but differ in that a large number of a firm's employees are eligible for these benefits.

Poison Pill

It provides the holders with special rights in the case of triggering event, such as a hostile take-over bid. If a deal is approved by the Board of Directors, the poison pill can be revoked, but if the deal is not approved and the bidder proceeds, the pill is triggered. Typically, poison pills give the holders of the target's stock other than the bidder the right to purchase stock at a steep discount. This makes the target unattractive or dilutes the acquirer's voting powers.

Bebchuk (2003) is aiming to use the bylaws to force a change on the issue of takeover defenses, especially the poison-pill bylaw provisions. He argues that this provision denies the shareholders the right to make their own decisions, and proposes that the poison-pill provisions be approved by a two-third majority of directors and they should expire within 3 years.

52.6.4 Anti-takeover Devices and Independent Outside Directors

Some argue that because of reputational concerns and fear of lawsuits, outside directors are likely to represent shareholders' interests effectively (Bhagat et al., 1987). On the other hand, it is argued that outside directors are more likely to be align themselves with the top management than shareholders, not only because the top management has great influence over those who sit on the board but also because non-management directors typically hold a trivial portion of the stock of the firm.

Brickley et al. (1994) examined how the shareholders react to poison pill when the corporate board is independent or not independent. If outside directors represent the shareholders' interest, the likelihood of using a poison pill to harm shareholders should decrease with the fraction of outsiders on the board. In this case, investors should react positively to the poison pill. In contrast, if outside directors represent managerial interests, the likelihood of using a poison pill to harm shareholders will not vary with the fraction of outsiders on the board. In this case, stock market's reaction will not depend on the board composition. They find a significant positive relation between the stock market reaction to the adoption of poison pills and the fraction of outside directors on corporate board. The results suggest that outsiders represent shareholder interests.

52.6.4.1 Poison Pill and Firm Performance

Do poison pills affect operating performance of the firm? A widely held view is that poison pill negatively affects firm performance. Danielson and Karpoff (2006) examine whether poison pills improve operating performance, and their findings suggest that firms experience modest operating

performance improvements during the 5-year period after pill adoption. These improvements occur for a wide range of firms, and are unrelated to specific adoption years or whether firms invest heavily in R&D. Their findings are, however, at odd with the widely held view that poison pills negatively affect firm performance.

52.6.5 Role of Institutional Investors in Corporate Governance

The main institutional investors are the pension funds, insurance companies, and investment companies. The institutional investors are especially concerned with the election of directors and they believe that they should have a right to nominate directors because they hold significant shareholdings in the company. In the case they have no say in nomination of election of directors, they express their concerns about corporate governance by selling their shares, which may not be good for the stock price of the company.

Institutional investors can provide a good monitoring over managerial activities because of strong shareholding. Additionally, they can play also a positive role in mitigating the agency problem. Their substantial influence on the company's management can be used to align management interests with those of the shareholders. Thus, they can reduce the agency problem by possessing resources and expertise to monitor the managerial and provide oversight functions. In this regard, Stapledon (1996, p. 17) writes that monitoring by institutional shareholders fits within a broad tapestry of devices and market forces which operate to reduce the divergence between the interests of managers and shareholders. Diamond (1984) believes that institutional investors can solve the agency problem because of their ability to take advantage of economies of scale and diversification, and by demanding greater accountability from management. Chung et al. (2002) argue that there will be less opportunistic earnings management in firms with more institutional investor ownership because the institutions will either put pressure on the firms to adopt better accounting policies, or they will be able to unravel the earnings management.

It is also argued in the literature that Institutional investors' intervention can produce higher financial returns. Institutional activism can bring financial rewards, as more efficient monitoring of company management aligns shareholder and manager interests and thus helps to the maximize shareholder wealth. Agrawal and Knoeber (1996) also emphasize that the involvement of institutional investors can have a positive effect on corporate financial performance. Bethel et al. (1998) also report that active blockholders lead to enhanced shareholder value.

Some authors have expressed the view that institutional shareholding may result in an increase in information asymmetry. It is argued that institutions can have access to privileged information, which will create an asymmetry between themselves and smaller shareholders. Institutions are actually not the shareholders, instead they represent the principals who are the shareholders. This situation thus creates an added agency problem. Not only does the shareholder (individual pension fund member) have to worry about the possible divergent objective of investee company management but they also have to worry about the activities of the pension fund managers. In fact, some authors argue that institutional shareholders support management instead of shareholders. In fact, Davis and Kim (2007) report that although mutual funds are no more likely to vote with management of client versus non-client firms, there is a positive relation between business ties and the propensity of mutual funds to vote in favor of management proposals. Pound (1988) argues that institutional investors have a tendency to help entrenched management by voting with the management team. Consequently, institutional shareholding may result in negative impact on the firm's long-term performance.

Institutional shareholdings may also lead to short-term profit maximization in order to make their returns look as healthy as possible in the short run. They may therefore pressure companies to focus on short-term profits rather than long-term profits. This can be detrimental to long-term company survival, as companies need to invest in long-term projects in order to ensure they grow and prosper in the long run.

52.7 Impact of Corporate Governance on Firm Performance and Disclosures

52.7.1 Firm Performance and Corporate Governance

The main objective of corporate governance is to monitor managerial activities and provide advice to management to improve firm performance so that shareholders' interests are protected and firm value is enhanced. Therefore, a question of interest is what type of corporate governance can achieve these goals. It is generally argued that an independent corporate will be more effective and enhance firm performance.

52.7.2 Problems Associated with Managers-Shareholders' Conflict

Though firm is influenced by several factors, but the most important factor is the managers-shareholders' conflict, which gives rise to the following three problems:

52.7.2.1 Free Cash Flow Problem
Shareholders would prefer that free cash flow is distributed in the form of dividends to them, but managers would prefer investing cash flows over the payment of dividends, even in

the absence of profitable investment prospects. Managers' preference is motivated by power, prestige, and higher salaries that, on average, are associated with managing a larger firm.

52.7.2.2 Risk Problem
Shareholders can diversify their risk through their portfolio choice, but managers cannot do so because they have a significant human capital investment in the firm. Thus, shareholders are willing to undertake risky projects. Managers are generally risk-averse than shareholders, and they are unwilling to undertake risky projects.

52.7.2.3 The Horizon Problem
Managers, on average, are more myopic than shareholders in making their decisions, because of the pressure to produce immediate results. "Short-termism" may drive managers away from necessary maintenance and R&D expenditures, and high-technology investment that are bound to have a longer payback period.

Because of these conflicts, some authors argue that managers may not invest in profitable projects which have long horizons. Consequently, the conflict is likely to result in lowering the operating performance of the firm in the long run. To overcome these problems, corrective action is needed to focus managers' attention on the main goal, i.e. to maximize shareholders' value through better performance. Broadly speaking, two types of mechanism are used to improve firm performance thus enhance firm value, and these are: monitoring of managers by corporate boards, proper advice and guidance by corporate boards, and development of incentives by the corporate boards to properly align managers interests with shareholders' interests.

52.7.3 Monitoring by Corporate Boards and Firm Performance

It is generally argued that proper monitoring of managerial activities is expected to improve firm performance, and some authors argue that outside independent directors will provide more effective monitoring of managerial activities to achieve the objective of enhancing firm value.

52.7.3.1 Independent Corporate Boards and Firm Performance
It is argued that outside directors, who are supposed to take care of shareholders' interest, can discipline management better, and thus provide a more effective monitoring. An effective monitoring is expected to results in a higher level of sales, fewer employees' turnover, higher labor productivity, lower selling and general administrative expenses, etc.

Cumulatively, these factors are expected to result in better firm performance.

Empirical evidence is, however, mixed on the role of independent directors in improving firm performance. Though some findings suggest that independent boards are positively associated with firm performance, others indicate that there is no significant association or negative association. It is argued that the appointment of independent directors would send a positive signal to the market on firm performance. Rosenstein and Wyatt (1990) evaluate market reaction to the announcements of outside board appointments, and find significant positive excess returns around the days of the announcements. They interpret their findings to show that the announcements of appointment of an outside director are associated with an increase in the shareholders' wealth. Fosberg (1989), however, reports no relationship between the outside directors and various variables used to gauge firm performance. In fact, to the contrary, he finds that firms with non-majority of independent directors had a mean ROE 1.1% greater than the firms with majority of independent directors. Overall, the findings show that the presence of outside directors does not enhance firm performance.

Fama and Jensen (1983) argue that the executive directors will have a positive impact on the firm performance. Inside executive directors are an important source of firm-specific information, and their inclusion on the board can lead to a more effective decision-making process. Morck et al. (1988), however, maintain that, when there is a high level of inside ownership, the executive directors may use their voting power to maintain their jobs (entrenchment) and maximize their benefits by designing their compensation packages. This will not enhance firm performance.

Findings by Hermalin and Weisbach (1991), however, show no significant association between firm performance and inside directors. They argue that inside and outside directors have their respective advantages and disadvantages. If each board is optimally weighted between insiders and outsiders, board composition will have no effect on firm performance. Rosenstein and Wyatt (1990), however, detect different market reaction to different levels of insider managerial ownership. Reaction is significantly negative when inside directors ownership is less than 5%. The reaction is significantly positive when the inside ownership level is between 5% and 25%. The reaction is insignificant when ownership percentage exceeds 25%. They interpret their findings to suggest that at low levels of inside ownership, the market infers that the addition of an inside director is likely to be an attempt to entrench the existing management, i.e. the existing CEO and hand-picked successor. Thus, negative reaction at the moderate level of inside ownership, where managerial interests are closely aligned with those of the outside shareholders, the expected benefits of the

specialized knowledge provided by an inside manager outweigh the expected costs of increase managerial entrenchment. Thus, a positive reaction at high levels of inside ownership, where insiders may have the voting power to insulate themselves from the scrutiny of outsiders, costs of the appointing insiders offset the benefits.

52.7.3.2 Financial Expertise on the Corporate Board and Firm Performance

The SOX requires that one of the outside directors on the audit committee should have accounting or financial expertise, but there is no direct requirement of expertise of outside directors on the corporate boards. The audit committee requirement indirectly implies that at least one outside director on the board should have financial expertise. Will financial expertise of independent directors lead to better firm performance? It is generally argued that the effect of independent director with expertise will depend on the nature of his/her expertise. It is generally expected that independent directors with expertise are likely to make the board more effective.

52.7.4 Alignment of Managers' Interests with Shareholders' Interests and Firm Performance

Corporate boards also motivate managers to enhance firm performance by aligning their interests with those of the shareholders. The common technique used for this purpose is providing ownership of the stocks to managers.

Alignment of interests is also possible through compensation system. The use of stock options in the compensation structure is expected to align the managers' interests with that of shareholders.

52.7.5 Financial Disclosures and Corporate Governance

Managers try to achieve different objectives through disclosures, especially voluntary disclosures, which may include the following: to send positive signals to the market, to create positive image for the company, to confirm or rebut existing information in the market, and to counteract rumors. Meaningful, reliable and timely disclosure must meet the following criteria: accuracy, reliability, appropriateness, completeness, clarity, and timeliness. Reliability of disclosures is important to provide credibility to information so that it can be used in the decision making process.

52.7.5.1 Transparency in Disclosures

Bushman et al. (2004) emphasize that transparency is an important aspect of disclosures. They argue that Information disclosed by management is an output from a multifaceted system whose components collectively produce, gather, validate, and disseminate information. They further differentiate between three aspects of transparency and these are: the financial transparency, the governance transparency, and the risk transparency.

Financial transparency refers to the comprehensiveness (intensity) of financial information disclosed and the timeliness of these disclosures. Comprehensive disclosures should meet the following three criteria:

First, *obfuscation* should be avoided. It is argued that disclosures can result in *obfuscation* when managers possess more private information and they are less forthcoming with their overall disclosures (including voluntary disclosures), and it creates higher information asymmetry. In case disclosures are not comprehensive, it is feared that analysts may be inclined to follow firms with more private information than publicly available information because potential rewards would be higher (Barth et al., 2001). Consequently, this type of information will have lower reliability.

Second, disclosures should not be *opaque*. Many firms are guilty of providing *opaque* (hard to understand and explain) disclosures, and such disclosures are not suitable for investment decisions, especially, when information relates to special purpose entities, stock option expensing, intangible assets and research and development.

Third, disclosures should be *timely*. The main issue involved in the timeliness of disclosure relates to disclosure of losses. Should they be disclosed without any time delay or with delay? Similarly, when gains should be disclosed? The timeliness of disclosures of gains and losses is referred to as *accounting conservatism*. Conservative accounting is generally provides more timely and reliable information. The reliability and timeliness of disclosures in turn determine the disclosure quality, and the disclosure quality builds credibility of disclosures in the financial markets.

52.7.5.2 Factors Influencing Transparency

Transparency of disclosures is influenced by the following factors: (1) monitoring effectiveness of the corporate boards, (2) ownership structure, and (3) political economy.

An effective corporate board should result in more comprehensive and timely information disclosures, which should be useful to investors to make informed judgments. What is an effective corporate board? An independent board, a board with expertise, or a board with not very busy directors. The number of meetings is reasonable to discuss different issues. Empirical evidence shows that independent boards are associated with higher voluntary disclosures. Chen and Jaggi (2000) show that there is a positive association between a higher percentage of independent directors and financial disclosures in Hong Kong firms.

The corporate ownership structure also plays an important role in disclosure transparency. There is no strong incentive for management to high transparency in disclosures when ownership is concentrated in the hands of family members, who are also control the firm's management. Transparency in disclosures is, however, important in firms with diffused ownership because public disclosures by the firms provide more reliable and cost-effective information to the shareholders.

The political economy represents a range of institutional arrangements that capture important relations between the government and economy, and these are: concentration of political power (autocracy), state corporate ownership (non-banks), state bank-ownership, costs of entry imposed on start-up firms, and risk of appropriations. It is argued that these factors also play an important in transparency of corporate disclosures.

52.7.6 Corporate Governance, Risk Assessment and Risk Disclosures

Risk assessment and risk disclosures have recently started receiving increased attention of managers, corporate boards, and also auditors. Without an effective risk assessment, companies are unable to prioritize and efficiently deploy their resources and develop reliable monitoring activities. Risk assessment includes both an evaluation of the inherent risks (e.g. impact and likelihood analysis), and an evaluation of the effectiveness of management's controls and risk management activities.

The goal of an effective risk assessment process is to identify coverage gaps and develop plans to remediate coverage deficiencies before they are exposed. The corporate board has multi-dimensional responsibilities in steering top management towards the right risk choices. The board should monitor the risk situation of the company systematically to identify and evaluate multiple sources of risk, and the following guidelines in the process of risk evaluation: (1) Take a portfolio view of corporate risks, (2) Be apprised more specifically of the major risks (for major risk combinations) that could significantly alter business perspectives, (3) Evaluate the way in which management has embedded risk management within the corporation, asking organizational questions, such as "do we need a chief risk officer", "how risk is being evaluated?"

Corporate disclosures should be in compliance with legal regulations and administrative rules, and additional it disclose risk information voluntarily which is not covered by the regulation but is important for investors to make their decisions.

Abstract

International banks have played a key role in the financial integration of global financial markets and the economic integration of countries. Their role as geographic intermediaries has helped send capital to countries and regions that previously had difficulty attracting funds. But because of poor risk and liquidity management, the banks also played a central role in the 2008–2009 financial crisis. European banks remain weakened by the Euro-Zone's sovereign debt crisis, as policymakers search for a resolution. This article presents a broad look at international banking since the 1960s, and, to a lesser extent, the role of financial institutions generally in world financial markets.

53.1 Introduction

International banks have played a key role in the financial integration of global financial markets and the economic integration of countries. Their role as geographic intermediaries has helped send capital to countries and regions that previously had difficulty attracting funds. But because of poor risk and liquidity management, the banks also played a central role in the 2008–2009 financial crisis. European banks remain weakened by the Euro-Zone's sovereign debt crisis, as policymakers search for a resolution. This article presents a broad look at international banking since the 1960s, and, to a lesser extent, the role of financial institutions generally in world financial markets.

This article comprises an introduction and three sections. Section 53.2 will discuss a brief history of the development of international banking activity in the United States, Europe, and Japan. Section 53.3 will report on historical trends in banking activity beginning in the late 1970s, and it will also assess how the financial crisis of 2008–2009 affected international banking activity. Section 53.4 will cover international banking regulation. This section will include a history of international banking regulatory efforts, which began in the 1970s. The most recent changes to the regulatory structure are defined in Basel III, which is the global response to the regulatory failures revealed during the "Great Recession." This section will also highlight some of the debate about this new regulatory architecture designed by the Basel Committee on Banking Supervision.

53.2 Aspects of International Banking History Since 1960

International banking grew in the 1960s and 1970s in the US, Japan, and Europe for some similar reasons across the three regions. Commercial banks faced slowing domestic growth and the declining profitability of domestic banking business, and, so, they looked for greater opportunities in foreign markets. There are, however, differences, which are discussed below.

J. Winder (✉)
Rutgers University, New Brunswick, USA

53.2.1 Japan

Burton (1983) describes the expansion of international banking in Japan. Pushed by increasing trade with the rest of the world, Japan's Ministry of Finance, beginning in the 1960s, began to allow greater expansion of Japanese banks in foreign markets. These developments marked Japan's ascendance as a global economic power. Initially, the expanding foreign banking was mostly lending to businesses, but from the mid 1970s onward, Japan's international banking presence expanded into consumer retail banking as well.

Along side the expansion of international banking that came from increasing trade, domestic economic conditions also played a role. Economic growth was quite rapid from the mid 1950s until the early 1970s. But following the first oil price shock in 1973, the trend rate of economic growth in Japan slowed, reducing the earning power of the banks. A less optimistic forecast for growth of the domestic banking market led the largest banks (the city banks) to expand their international operations. Of course, global economic growth also slowed following the first oil price shock. Global banking activity was also diminished by the failure of the German Herstatt Bank in 1974 and the second oil price shock in 1979. In order to gain market share in international banking at such a difficult time, Japan banks pushed international expansion by aggressively competing on loan terms. Commercial lending spreads offered by Japans banks were much narrower than spreads on comparable loans offered by US and European banks. The strategy was successful. By the early 1980s, Japanese banks ranked second in terms of international lending to US banks.

53.2.2 The United States

Brimmer (1975) assesses some of the special characteristics of the US expansion into international banking. The expansion of US banks into international banking needs to be viewed against the backdrop of the Bretton Woods currency agreement that prevailed from just after World War II until the early to mid 1970s. Japan's Ministry of Finance supported the growth of international banking. The US took a different approach. US policies were aimed at regulating and managing commercial bank lending to foreigners as a tool to reduce the widening balance of payments deficit. The persistent widening of the US international payments deficit in the early 1970s made sustaining the fixed rate currency system, with the dollar as its foundation, more difficult. As part of this program to manage banking sector foreign lending and investments, the US had from the early 1960s to 1974 a program of voluntary foreign credit restraint (VFCR) managed by the Federal Reserve and an interest equalization tax, which was intended to reduce the returns from investing in foreign markets. Despite efforts by President Johnson to tighten the restrictions on private foreign financial flows, the program did not lead to a narrowing of the US balance of payments deficit. The policies, perhaps predictably, had the reverse effect of encouraging the off-shore growth of US banks.

Following the removal of VFCR limits in 1974, there were two key issues for US policymakers (Brimmer, 1975). First, how should the rapidly expanding non-US banks be treated, given that the US lacked national banking? To address this issue, Congress passed the International Banking Act of 1978. The goal of the IBA of 1978 was to bring foreign banks under the same set of federal regulations as those that applied to domestic banks. There was still, however, a big advantage for foreign owned banks: they could operate in more than one state, while US banks could not.

The second issue was, were there workable policies to slow the foreign expansion of US banking corporations? Along with the VFCR and interest equalization tax, deposit reserve requirements and FDIC deposit insurance added to the cost of lending from the US. Foreign branches of US banks could avoid these costs. And, so, the result was a rapid expansion of US banking companies into London and other centers like the Cayman Islands and Bermuda in the 1960s and 1970s. US banks also had to contend with deposit rate ceilings that compromised their ability to compete for international funds. International Banking Facilities (IBFs), first proposed in 1978 and approved by the Federal Reserve in 1981, were intended to bring offshore banking activities back onshore in the US. The IBFs allowed US banks to operate free of these regulations provided they took deposits and made loans only to non-US residents. The IBFs did not represent new office locations or buildings. Rather they were a second set of books for banks that did international business.

53.2.3 Europe

Ross (1998) describes the efforts in the 1960s to promote international banking in Europe through banking clubs. The clubs were groups of large banks whose goal was to give member banks the ability to do business in other countries without having offices in foreign countries. The goal of the clubs was to slow the advance of US banks into European markets.

The banking clubs represented a business strategy for participating in international banking that had three parts. First, was the belief that the clubs would foster increased European economic integration. In September 1957 Belgium, France, Germany, Italy, Luxembourg, and the Netherlands signed the Treaty of Rome forming the European Economic Community. The Treaty made a firm commitment to the principle of competition, including the free

movement of labor and free trade in services (Dutta, 2007). It was hoped the banking clubs would build on this foundation and further enhance the process of European economic integration. The second reason for the founding of banking clubs was to meet the challenges posed by a growing American business presence in Europe. Between 1962 and 1969 deposits at American banks in London increased by almost 20 times, and by 1972 they had captured about 10% of all loans to UK residents (Ross, 1998). American banks and American businesses more generally were seen not only as a threat to European capitalism, but also to European culture.

The third reason for the development of banking clubs was that clubs represented the best way to participate in opportunities offered by the development of international financial markets. There were three options for European banks to respond to the challenge of the growing American banking presence (Ross, 1998). First, they could set up a branch system across countries, essentially following the American approach. Second, European banks could merge, forming multinational entities. And third, they could find partners with whom they could become increasingly integrated over time.

The first choice was difficult to achieve. Establishing a successful international branch system takes time, which European banks did not have given the superior managerial ability of the American banks. The second choice of merging to expand size and capability was difficult to achieve because of differences in tax laws and regulatory policies across countries. The third choice was the only real option. Find a group of partners to combat, over the short-term, America's forceful presence in European finance and commerce, and expect that over time the banks in the club would become more integrated. This was especially so since it was believed that economic integration of Europe would gain momentum. The idea was that by joining forces European banks could offer superior service to clients and compete successfully against US banks (Ross, 1998).

The system of banking clubs was failing by the mid 1970s. There were conflicts of interest and business opportunities as club members began to compete against each other. Progress toward European economic union also dimmed during these years. The differences mentioned above in tax and regulatory policies, and also exchange controls, made progress toward an economic union slow.

53.3 Trends in International Lending 1977 to 2011

This section looks at trends in international data for commercial banks and financial institutions more broadly. The BIS international banking database begins in 1977 for many countries, but not until the mid 2000s for other nations. BIS data series for financial institutions also begin at various times. We will assess trends over two time periods: the full 1977–2011 interval, and a shorter interval covering the financial crisis of 2008–2009.

53.3.1 International Banking and the Relationship to Economic Activity

BIS data on international banking begin in 1977 for a large sample of countries, which are mostly Western Europe, the United States, Canada, and Japan. The sample expands to cover more emerging markets after 2000. Table 53.1 looks at the growth of international assets and liabilities for all countries and for the US, Europe, and Asia. Data series for many Asian countries do not begin until the mid-2000s.

The 5-year time periods reported are based around year end 2007, when the dollar amount of international assets and liabilities peaked prior to the near collapse of the global financial system in 4Q/2008. There were two periods of rapid expansion of international banking, 1977–1982 and

1982–1987, prior to the acceleration that preceded the Lehman Brothers bankruptcy in September 2008. The first period corresponded to the inflationary period that resulted from the second oil price shock in 1979 and years of easy US monetary policy. There were two US recessions during this period, as the Federal Reserve under Paul Volcker shifted from targeting interest rates to targeting nonborrowed reserves. From 1982 to 1987, interest rates were generally declining, while the global economy was strengthening.

Table 53.1 also shows the acceleration in international lending that occurred during the credit expansion that preceded the financial crisis of 2008. From December 2002 through December 2007, international banking activity expanded at roughly similar rates across Europe, Asia, and the United States. International assets and liabilities increased from 16% to 19% per year. But, from the peak in the dollar amount of international assets and liabilities outstanding in December 2007, there has been a net decline in the global totals. Global international lending is down 3% through the first quarter of 2011. International lending in Europe declined significantly more than the global total, perhaps reflecting the large amounts of lending to troubled European governments.

We can compare the credit burst preceding the 2008 financial crisis to other periods of rapid international banking growth. Specifically, international banking activity experienced a sharp acceleration relative to economic growth beginning around 2000. Graph 53.1 shows international banking relative to global economic activity. The graph was created as follows. A ratio of international banking activity to global economic growth was created using BIS data on international lending and IMF data on inflation and industrial production. The IMF data cover the developed world, which produced most of the international banking activity during the entire 1977–2011 period. The international banking data are first deflated by the CPI for

developed countries to create a "real" lending total, which can then be compared to production, also a real variable. An index was then created for real lending matching the base period (2005) used for the IMF industrial production index. We then take the ratio of the real lending index to the index for industrial production of the developed countries. If real lending is increasing relative to the pace of global production, then the ratio will be increasing.

The graph reveals a gradually increasing trend in international banking relative to economic activity until around 2000, when a sharply increasing trend begins. Some of acceleration can be attributed to the increased number of countries participating in the BIS banking sample. But, it can be seen from Table 53.2 there was an acceleration in international banking activity for the group of countries covered by the banking data which begins in 1977. For example, the data for the US, Canada, France, Germany, Italy, Japan, and the UK also show an acceleration beginning in the 2002–2007 period. That is, the graph would have a similar profile if only countries whose data begin in 1977 were used to create the graph. Many versions of this graph were

created. Some used international assets, some international liabilities, and some did not make any adjustment for inflation in the developed countries. The analysis always produced a graph with a similar look.

In one calculation of the lending to economic activity ratio, we used the IMF annual series for world nominal GDP, measured in US dollars, which begins in 1980. The numerator of this ratio was BIS international loans outstanding, measured in current US dollars, and the denominator was world nominal GDP. The graph has the same general shape as the graph based on global industrial production. Regardless of the computational method used, the graph has the same key feature: an intensifying use of international lending and borrowing beginning around 2000.

Some of the more intensive use of international credit reflects globalization, the expansion of world trade and financial flows relative to the size of the global economy. There are also many current analyses, some by academics and some by financial industry researchers, which conclude the more private sector deleveraging is needed in the industrialized world before balance sheets are healthy again. It is interesting to note that our measure of international banking activity relative to global production points in the same direction. International assets and liabilities outstanding are still very high relative to the pace of global economic activity, suggesting that more global deleveraging is needed before the world's financial system is strong again.

The regional data in Table 53.1 and the country data in Table 53.2 illustrate a key point about trends in international banking activity since the end of 2007. Activity has declined in the developed countries, while it has expanded in emerging market nations. The aggregates for Europe and Asia presented in Table 53.1 and the individual countries reported in Table 53.2 show this. Some of this probably reflects the problems affecting European banks, as

mentioned earlier. But, it could also reflect the growth of financial markets in IEM countries.

53.3.2 The Dominance of Developed Country Financial Institutions in International Debt Markets

Financial institutions, that is, commercial banks, investment banks, and insurance companies, from developed countries dominate the international debt market. Table 53.3 reports the share of total financial institution international debt outstanding issued by developed and developing nations. The data begin in 1987. Five-year intervals are again reported, while the most recent quarter 1Q/2011 is also included. The figures show that financial institutions in developed countries had issued about 96% of total financial institution international debt outstanding in 1987 and had roughly the same market share in March 2011. This was a surprise. Given the trend in emerging market economic growth relative to economic growth in the developed world, we had thought that there would be greater penetration of emerging market financial institutions over the past 25-year period. But, the data just reinforce the notion that acquiring access to global debt markets is difficult to achieve for most emerging countries. Gaining access to global capital markets is a process that takes many years, as described in Eiteman (2010).

International debt outstanding issued by Asia Pacific financial institutions actually declined slightly from 1987 through early 2011 as a share of the total international debt obligations of financial institutions. BRIC countries did not gain market share in international debt markets, and the newly created "MIST" group of countries comprising Mexico, Indonesia, South Korea, and Turkey had a declining

share. The developing region with the most success gaining access to global debt markets is Eastern Europe, Russia, and Turkey. Latin America financial institutions also had some modest success penetrating global debt markets.

53.3.3 International Money Market Instruments and the Currency of Issue

Global financial institutions have come to dominate the market for international short-term debt, most of which is commercial paper. Over 90% of international debt instruments with original maturities of less than 1 year were issued by financial institutions as of March 2011, which is up significantly from 38% in December 1990.

Table 53.4 begins at the end of 1990. The international money market instruments issued in what is called "euro" represented 10% of total issues outstanding. This is, of course, 8 years before the introduction of the euro on January 1, 1999. The figures before January 1, 1999 represent international money market debt issued by the countries in the Euro-Zone as of its starting date. This table also includes data for year end 1998 and for year end 1999. In just its first year, the euro captured a significant share, almost one-third of the international short-term debt market. The most recent data put the euro as the currency of issue for about 41% of international short-term debt. The dollar was the currency of issue for almost 78% of total international money market debt outstanding when the data begin in 1990. Figures for 1Q/2011 show the dollar share to be about 37%. Interestingly, the share of international short-term debt issued in yen

increased substantially during the 1990s before falling sharply in the past 10 years. On a trend basis, the share denominated in pounds has risen since the data begin and since the introduction of the euro. The rise of the euro and the pound have, thus, come at the expense of the dollar and the yen.

While the long-term data show a rising trend for euro-denominated international money market liabilities, and a declining trend for dollar-denominated liabilities, data during the 2008–2009 financial crisis and beyond reveal a different story. The share of international money market debt issued in dollars increased. The figures in Table 53.5 begin in June 2008, the quarter before the financial crisis started. The figures also cover Greece's sovereign debt problems in the spring of 2010 and Ireland's crisis in the fourth quarter of 2010.

The share of international money market obligations issued in euro declined at year end 2008 as the financial crisis reached its most intense period in January 2009 when the Merrill Lynch/Bank of America merger almost failed. Once the depth of the crisis was reached in the first quarter of 2009 and global equity markets recovered sharply, the dominance of the euro over the dollar reasserted itself, with the euro reaching 51% of total international money market debt outstanding in September 2009. Since this peak, the euro share fell to just 41% in March, 2011, reflecting to some extent the Euro-Zone sovereign debt crisis that is still unresolved.

What is interesting is that since the Euro-Zone's sovereign debt problems first surfaced in Greece in the second quarter of 2010, the share of dollar-denominated money market debt has been steady at around 36%. The decline in the euro share from 45% to 41% has been offset by an

increase in the amount of international money market debt denominated in sterling from 11% to 15%.

53.3.4 International Notes and Bonds: By Type and Currency of Issue

Table 53.6 shows the amount of international note and bond issuance due to the activities of financial institutions. The BIS data begin in 1993. The table shows figures representing floating rate debt, straight debt, and equity-linked debt, which is primarily convertible securities.

The data show that international notes and bonds issued by financial institutions comprised 41% (line 4) of the total international long-term debt outstanding when the data begin in December 1993. Once again, financial institutions came to dominate these markets over the years, reaching almost 75% of total international long-term debt outstanding in March 2011. These figures and those for short-term debt demonstrate that international financial institutions are the dominant players in the international debt securities markets.

The share of all three types of international debt instruments increased for financial institutions during the period covered by BIS data. Financial institutions dominate the markets for floating rate and straight international debt securities. The share of equity-linked debt also increased, but the largest issuer is still corporations.

The share of international notes and bonds denominated in dollars increased from 41% in 1993 to over 50% during

the years to 2000. This period included the tech bubble and one of the longest periods of sustained strong real US GDP growth and low inflation on record. Over the subsequent decade the dominance of the dollar gave way to increased issuance denominated in euros. The most recent data, for 1Q/2011, show that 45% of international notes and bonds outstanding are denominated in euros versus 38% for the dollar.

How did these trends hold up during the financial crisis of 2008 and the ensuing sovereign debt crises of Europe? Table 53.7 reveals some of the answer. This table begins in June 2008, just as did the table for international money market debt. The dollar gained share during the crisis period, while the euro lost some market share, just as occurred for international money market instruments.

53.3.5 The 2008–2009 Financial and European Sovereign Debt Crises

The world has suffered through two major financial crises since the autumn of 2008. The 2008 financial crisis is still affecting the economies of developed nations because private sector balance sheets still have too much leverage. And the Euro-Zone has yet to find a credible program to resolve the debt problems of several governments. The direct exposure of European banks to these governments and the indirect exposure of US banks, through interbank loans to European banks, have led to the underperformance of the financial stocks relative to broad market indexes.

To what extent have these crises affecting developed Western nations led to contagion in the banking sectors of emerging market countries? The answer is "not much" according to IMF banking data. Series of bank liabilities to non-residents, excluding liabilities to non-residents on the balance sheets of central banks, were created for emerging countries that have previously experienced banking or currency crises. The group includes Mexico, Brazil, Argentina, Chile, and Peru in Latin America. And, for Asia, this sample includes Indonesia, South Korea, Malaysia, and Thailand. The figures begin in 2007, just prior to the onset of the financial crisis (Table 53.8).

The constructed series show that during the worst of the financial crisis, the end of 2Q/2008 through 1Q/2009 period, there was indeed capital flight from the banking systems of most of the countries in this group. Brazil, Argentina, Chile, Peru, Indonesia, South Korea, and Malaysia all experienced net outflows of funds owed to non-residents, as might be expected in a severe financial crisis. For many of these countries, the outflows continued for 3 months after global equity markets began to recover in March 2009.

It is interesting to compare the fund flows from the 2008 financial crisis with the fund flows during the European sovereign debt crisis, which began in the spring of 2010, when Greece was close to defaulting on its sovereign debt. From the end of 1Q/2010 through 1Q/2011, almost every country experienced net inflows into its private banking system. Indonesia is the only exception. But smoothed data show that private banking system liabilities to non-residents in Indonesia were, on average, higher in the year after the Greek crisis began to unfold than they were in the year before the crisis began. Clearly, investors view Europe's

problems as not having a significant effect on the banking systems of emerging market countries.

Looking at the entire period from the end of 2Q/2008 through the end of 1Q/2011, the same point can be made. Seven of the nine countries in this sample had larger foreign liabilities in their private banking systems, suggesting that credit concerns from the Great Recession and the European debt crisis did not have lasting impacts on emerging market banking systems.

53.3.6 Balance Sheet Ratios for Global Banks

Regulatory authorities reacted to the financial crisis of 2008 with new proposals to regulate the global banking system. These new regulations, known as Basel III, will be discussed in the next section. For now, we set the stage for an assessment of the new regulatory architecture by focusing on some key measures of capital adequacy before, during, and after the Great Recession. The figures come from Bloomberg.

Table 53.9 reports several measures of capital adequacy for a sample of ten global banks: the five largest US commercial banks and the five largest European commercial banks. The time period covered is from year end 2000 to year end 2010. Three measures of capital adequacy are reported: (1) the tangible common equity ratio, (2) the BIS Tier 1 capital ratio, and (3) the BIS total risk-based capital ratio.

The ratios and their components are defined as follows:
Tangible common equity capital ratio: tangible book value as a percent of tangible assets.

Table 53.9 Capital adequacy ratios for selected global banks (percent, at year end)

Source: Bloomberg

Tier 1 capital: this category includes the book value of common stock, retained earnings, and non- callable, non-cumulative preferred shares.

Tier 2 capital: this category includes subordinated debt, loan loss reserves, and non-callable cumulative preferred shares.

Risk-Weighted Assets: Weights determined by an asset's credit risk.

(See Saunders 2011 for more detailed definitions.)

The Tier 1 capital adequacy ratio is defined as Tier 1 capital divided by risk-weighted assets, and, through the period covered in the table, this ratio must be at least 4%.

The total regulatory capital ratio is defined as Tier 1 plus Tier 2 capital divided by risk-weighted assets, and, through the period covered in the table, this ratio must be at least 8%. The global regulatory structure is covered in detail in Section 53.4.

The figures in the table make an important point. This group of large banks satisfied the Tier 1 and total risk-based capital standards throughout the 2000–2010 period. This was especially true during the crisis years of 2008 and 2009. None of the banks in this sample missed either of the BIS capital standards when the financial crisis was at its most intense point at the end of 2008.

The tangible common equity ratio (TCER), which was not included in either the Basel I or II accords, reveals a banking system under considerably more stress than portrayed by the Tier 1 and total risk-based capital ratios. It is fair to say that the European banks in our group had lower TCERs than did the group of US banks. Of the largest banks, only one US bank had a TCER below 2% at the end of 2008, while only one of Europe's largest banks had a TCER above 2%.

53.4 Basel III and the Regulatory Response to the Financial Crisis of 2008

This section traces the history of international banking regulation from the formation of the Basel Committee on Banking Supervision in the 1970s through Basel III. This section also includes summaries of key criticisms of Basel III.

53.4.1 A Brief History of International Banking Regulation

Jablecki (2009) relates the beginning of a determined effort to create an international banking regulatory structure to the 1974 collapse of two international banks: Franklin National in the US and Bankhaus Herstatt in Germany. A change of controlling interest in Franklin National from an American industrialist to an Italian financier led the bank into significant foreign currency speculation (among other risky practices) that ultimately led to insolvency. The Herstatt failure highlighted, as never before, counterparty/settlement risk. Forced into liquidation by German regulators, the bank failed to make US dollar payments after receiving deutschemarks from clients. The international nature of the problems that ultimately brought down both banks and threatened the global financial system focused policymakers on the growing size of cross-border capital flows, and the increased integration of global financial markets. Banks whose domestic activities might be adequately supervised by national authorities, might have international businesses that were inadequately regulated, potentially threatening the stability of the global financial system.

Recognizing the potential threats posed by the increasing size and interconnectedness of global financial transactions, the heads of the G-10 central banks established the Basel Committee on Banking Supervision (BCBS) in 1974 under the auspices of the Bank for International Settlements (BIS). The BCBS was then and remains the key policy developing entity for the global financial regulatory effort.

Khan (2002) takes a more endogenous view of the origins of international financial regulation. He focuses on deregulation, technology, and financial innovation as the primary forces behind the push to develop a global financial architecture in the 1970s and 1980s. First, the lifting of deposit rate ceilings in the US and the collapse Bretton Woods fixed exchange rate system occurred during a period of high and unpredictable inflation. This unstable economic environment created a demand for hedging tools, possibly denominated in non-dollar currencies. Second, technology and communication advances blurred the long prevailing barriers between banks and nonbanks, which intensified competitive pressures across the whole of the global financial industry. Third, the globalization of commercial banking led to competition between domestic and international banks, sparking debates about differences in regulations among banks across national borders.

The first action taken by the BCBS was in 1975. The Basel Concordat proposed that the country in which a bank is doing business, and not the bank's home country, would be the regulatory authority for liquidity and solvency issues. The activities of foreign banking subsidiaries would be regulated by the host country and not the parent's home banking authority (Jablecki, 2009).

The next policy from the BCBS was the Basel Accord of 1988, otherwise known as Basel I. Basel I established the internationally recognized capital adequacy standards that are reflected in the Tier 1 and total risk-based capital ratios presented in Table 53.9 above. The G-10 governments quickly adopted these standards, and by the late 1990s Basel I had been implemented in over 100 countries (Jablecki, 2009). The impetus for global capital adequacy ratios reflected concerns that national regulators would be tempted to relax capital standards during periods of financial stress, thus weakening the balance sheets of domestic banks. To remove this temptation, global standards were necessary. The two capital adequacy ratios would act as constraints on the expansion of bank credit. It was not the monetary authority that determined how fast bank credit could expand, it was the capital adequacy rules imposed by regulators (Disyatat, 2008).

Basel I was the first step on the road to a coordinated regulatory structure that could strengthen the banking systems of the industrialized nations. But, it did have deficiencies. First, it dealt with credit risk, but not other types of risk, such as market, interest rate, or operational risks. So banks had an incentive to perhaps take more market and interest rate risk than they would otherwise take. And because the Accord focused only on credit risk, regulators could not be confident that banking stability was enhanced. Second, it gave banks an incentive to economize on capital. That is, banks can increase their total capital ratio by either acquiring more capital or by restructuring their balance sheets to reduce risk-adjusted assets. One way this occurred was through asset securitization. And because it is easier to securitize higher quality assets, banks kept on their books the riskiest assets in any particular risk category (Balin, 2008).

Also, many banks came to believe that if they satisfied the Tier 1 and total risk-based capital standards, they had done all that was needed to achieve stability (Balin, 2008). It is clear from the data in Table 53.9 and the events of 2008 that just achieving, and even exceeding, the required BIS capital adequacy percentages does not eliminate the risk of a bank facing extreme financial stress.

Another important consequence of the Basel I risk-based capital rules was the procyclicality of bank capital. A 1999 BIS study covering G-10 countries concluded that bank capital is sensitive to the business cycle. Recessions tend to diminish bank capital, and so contribute to a reduction in bank credit just when new lending is needed. And bank capital tends to increase in expansions, tending to increase credit expansion, just when a slowing in lending is needed to maintain macroeconomic balance (BIS, 2011). This point is specifically addressed in Basel III, which is discussed below.

The deficiencies of Basel I sent the Basel Committee back to work to accomplish two goals. First, broaden the earlier rules so national regulators would focus on other aspects of banking risk, not just credit risk. And, second, make the asset risk-weighting categories more accurate, so securitization did not leave balance sheets riskier. For example, under Basel I corporate loans had a risk weight of 100%, regardless of whether the borrower was a AAA credit or a BBB credit. Under Basel II, weaker corporate borrowers have higher risk weightings (Saunders, 2011).

In 1999, the BCBS put forward a three-pillar approach to regulating banks, which was known as Basel II. Pillar 1 is Regulation, that is, the capital adequacy requirements set by regulators. Pillar 2 is Supervision, which covers enforcing regulations and monitoring the health of banks on an ongoing basis through regular contact between supervisors and bank management. Pillar 3 is Market Discipline, which promotes the disclosure of information so markets can accurately price a bank's risk, and, therefore, enforce good behavior. Basel II shifted the emphasis of bank regulation away from capital adequacy ratios and toward supervision and market discipline (Khan, 2002). In the aftermath of the 2008–2009 financial crisis, regulators returned to quantitative rules as the key safeguards of banking system stability.

53.4.2 The Failure of Basel II to Prevent Financial Crisis

While the Tier 1 and total risk-based capital ratios were important steps in standardizing global capital adequacy ratios, and the three pillars of Basel II broadened the scope of bank supervision, they did not prevent, nor did they signal, the near collapse of the global financial system that occurred in late 2008. This point is illustrated by the figures in Table 53.9, as discussed above. None of the banks in the sample failed to meet the Tier 1 or total capital ratio standards for year end 2008, when the crisis was most intense. Yet, many US financial institutions required central bank and federal government support to survive. According to documents released by the Federal Reserve and analyzed by Bloomberg, the Fed secretly lent about $1.2 trillion to US and European financial institutions in late 2008 to prevent a global systemic failure (Keoun, 2011).

Identifying the causes of the "Great Recession" provides an understanding of the motivations behind Basel III. Economics Europe (2010) lists several causes of the financial crisis.

(a) Regulatory policies were inadequate, particularly with regard to risk management.
(b) The capital banks were required to hold was inadequate, allowing banks to build up too much leverage.
(c) Banks had become dangerously illiquid.
(d) Countries did not have deposits safety systems that were seen as credible by the public.
(e) Procedures for resolving bad loans and investments were inadequate.

Other factors frequently mentioned as contributing to the crisis include:

(f) US Federal Reserve policy was too easy, creating an environment that encouraged excessive risk taking.
(g) Managers failed to understand the risks of funding illiquid assets in the repo market.
(h) The risks of off-balance-sheet activities were not fully reflected in BIS capital requirements.
(i) Stress testing of balance sheets by regulators and banks was inadequate.

This list of regulatory and managerial failures highlights the problems the BCBS addressed when the committee revised the regulatory structure for international banks.

53.4.3 Basel III

The Basel III policies emphasize quantitative standards for measuring and monitoring the financial health, both short-term and long-term, of internationally active banks. The three pillars of Basel II are still in place, but Pillar 1 has been significantly strengthened. Capital adequacy standards are toughened, and several new regulatory rules are added to improve liquidity. The intent of Basel III is clear: reduce the leverage creating potential of the international banking system, and provide for liquidity adequate to withstand both immediate and longer-term funding crises.

The major changes brought by Basel III are summarized below and in Table 53.10 (BIS, 2011).

(a) The Tier 1 capital minimum standard will be raised from the current 4% to 6% of risk-weighted assets by January 1, 2015. Within this requirement, Common Equity Tier 1

Table 53.10 Summary of Basel III requirements (all dates as of January 1)

	2011	2012	2013	2014	2015	2016	2017	2018	2019
Min. common equity ratio			3.5%	4.0%	4.5%	4.5%	4.5%	4.5%	4.5%
Capital conservation buffer						0.625%	1.250%	1.875%	2.5%
Min. common equity plus			3.5%	4.0%	4.5%	5.125%	5.750%	6.375%	7.0%
Capital conservation buffer									
Min. Tier-1 capital ratio			4.5%	5.5%	6.0%	6.0%	6.0%	6.0%	6.0%
Min. total capital ratio			8.0%	8.0%	8.0%	8.0%	8.0%	8.0%	8.0%
Min. total capital plus			8.0%	8.0%	8.0%	8.625%	9.250%	9.875%	10.5%
Capital conservation buffer									
New ratios:									
Leverage						2015: disclosure begins			
Liquidity coverage	2011: observation period begins					2015: Introduce minimum standard.			
Net stable funding	2011: observation period begins							2018: introduce min. standard	

Source: BIS

must be at least 4.5% of risk-weighted assets at all times when the transition period ends in 2015.

(b) A capital conservation buffer is imposed, increasing from 0.625% on January 1, 2016 to 2.5% as of January 1, 2019. The purpose of the capital conservation buffer is to "ensure that banks build up capital buffers outside times of periods of stress which can be drawn down as losses are incurred." (BIS, 2011, page 54). The intent is to force banks to reduce dividend payments, share buy-backs, and employee bonuses when minimum capital requirements might not be satisfied.

(c) The minimum total capital ratio remains at 8%, but the addition of the capital conservation buffer puts the total capital plus conservation buffer ratio at 10.5% when the measure is fully phased in on January 1, 2019.

(d) Along with the capital conservation buffer, national regulators may impose a countercyclical buffer when "excess aggregate growth is judged to be associated with a build-up of system-wide risk…." (BIS, 2011, p. 57). This buffer can vary between 0% and 2.5% of total risk-weighted assets. The countercyclical buffer is intended to mitigate the procyclical nature of bank capital. It can be reduced or removed when the business cycle slows.

(e) A leverage ratio is introduced because many banks had excessive on- and off-balance sheet leverage in the quarters prior to the onset of the financial crisis. This enormous build-up of leverage occurred at the same time that many banks had strong risk-based capital ratios. Reducing leverage caused banks to sell assets, which drove asset prices down further, leading to declines in bank capital, and diminished credit availability, which made the contraction of economic activity more pronounced. The BCBS will test a leverage ratio based on the new definition of Tier 1 capital, and it will also test alternative ratios where the capital measures are Tier 1 common equity and total risk-based capital.

The exposure measure used in the denominator is non-risk-weighted. The leverage ratio is intended to be a simple, transparent, and supplementary measure to the risk-based capital ratios. (BIS, 2011, p. 61.)

Basel III also announces two minimum standards for funding liquidity.

(f) The Liquidity Coverage Ratio (LCR) is intended to ensure that a bank can meet its liquidity needs for a 30-day interval under a scenario of significant stress. The ratio is defined as,

$$LCR = \frac{\text{stock of high} - \text{quality liquid assets}}{\text{Total net cash outflows over the next 30 calendar days}} \geq 100\%$$

This short-term liquidity ratio represents a significant change from previous regulatory rules, for banks are expected to satisfy this requirement on a continuous basis, and the stress scenario contains many of the shocks that occurred during the financial crisis. That is, banks must now maintain holdings of high quality short-term liquid assets assuming that many of the conditions that prevailed in 2008–2009 might recur. For example, the stress scenario includes: partial losses of retail and wholesale funding, a potential downgrade of up to three notches, unanticipated draw downs of unused credit lines the bank has provided to clients, increased collateral haircuts in repo markets, and the partial loss of available repo financing for some assets (BIS, 2010).

(g) The Net Stable Funding Ratio (NSFR) is intended to insure that long-term assets are funded with an adequate stream of stable liabilities over a 1-year horizon. The goal is to reduce reliance on short-term sources of funding at times when liquidity is inexpensive and readily available. And, just like with the LCR, this ratio is calculated under a stress scenario. The long-term stress

scenario includes a significant decline in profitability, a potential debt downgrade, and a material event that undermines the creditworthiness of the bank (BIS, 2010). This ratio is defined below, and once again, at least 100% coverage of the need for longer-term stable funding is necessary.

$$\text{NSFR} = \frac{\text{Available amount of stable funding}}{\text{Required amount of stable funding}} \geq 100\%$$

53.4.4 Conclusion

Basel III imposes significant new constraints on the behavior of global banks. Indeed, the excessive leverage ratios of 2008 are now impossible to achieve given the minimum Common Equity Ratio of 4.5% that will be effective in 2015. This is all much to the satisfaction of central banks and regulators. But what are the costs of this new, heavier hand of regulation? Are there other ways to improve the supervision of global banks?

Standard and Poor's (2010) notes that the definition of high quality liquid assets in the numerator of the Liquidity Coverage Ratio is "significantly more restrictive than the standards central banks typically maintain for collateral eligibility under the liquidity facilities that serve as a key backdrop to the banking system." (S&P, 2010, p. 4.) S&P also notes that the LCR assumes that all unused credit facilities are drawn down by clients, while banks are assumed not to be able to use any of their credit lines. The S&P fear is that imposing this condition might impede the flow of funding through the interbank market.

S&P (2010) also believe that the Net Stable Funding Ratio, by diminishing the traditional bank asset/liability mismatch, could diminish banks' maturity transformation role in the economy.

The Institute for International Finance has written extensively about the practices it believes will best foster financial stability. Its focus is on developing a set of best practices for banks to manage risk and increase transparency, rather than on higher capital requirements. The IIF states, "The purview of the macroprudential authority needs to extend beyond the existing regulatory perimeter. It must have access to all the information needed to assess risks to financial stability…." (IIF, 2011a, p. 10). And "Regulation alone cannot create a safer financial system—it can only do so if partnered with improved industry practices and a strengthened global supervisory system." (IIF, 2011b, p. 11.)

The IIF believes that a strong and open relationship between banks and their supervisors is the best policy for maintaining financial stability. The IIF goes so far as to advise that banks take the initiative in providing necessary information to regulators. And banks should be willing to bear some cost, if doing so improves the quality of supervision. (IIF, 2011b).

Another study prepared for the City of London Corporation by Europe Economics is more critical of Basel III. For them, the key issues are the development of resolution regimes, especially those that cause bond holders to take losses and liquidate holdings, and the maintenance of sufficient liquidity. They do not believe that a convincing case for higher capital requirements was made (Europe Economics, 2010).

Much attention will be directed in coming years to the effects of Basel III on the profitability of international banks. The phase-in of many aspects of Basel III, such as the new Tier 1 capital ratio, the LCR and the NSFR, will give the BIS time to understand how the new regulatory structure affects both earnings and the volatility of earnings. Regulators will also need to assess how significantly increasing the capital and liquidity costs of lending affect the availability and terms of credit. Credit growth is necessary for economic growth throughout most of the world. Regulators will need to weigh the benefits of a more stable global financial system against the potential economic costs of diminished credit availability.

Abstract

Hedge funds are quite likely the most important investment vehicles in the financial markets today since they control roughly $2 trillion in assets and account for the bulk of trading volume across many asset classes. This article provides its readers a firm understanding of the hedge fund industry, their most common investment strategies and the trends shaping the field. It also provides detailed examples of three specific hedge fund strategies: dual share class arbitrage, pairs trading, and activist investing.

Hedge funds in their various forms may play a useful role in most individual and institutional portfolio due to the prospect of higher risk adjusted returns, as well as the lack of correlation with traditional stock and bond portfolios. In short, they may improve the Markowitz Efficient Frontier of most portfolios. The industry is still evolving and its continued growth will likely result in the compression of fees, increased liquidity, improved transparency, and increased regulation.

Keywords

Hedge funds • Hedge fund history • Hedge fund strategies • Hedge fund trends

54.1 Introduction

Hedge funds are quite likely the most important investment vehicle in the financial markets today. Their managers such as George Soros, John Paulson, James Simons, and Steven Cohen, are some of the most closely watched and highly paid financial professionals in the world. Hedge funds manage roughly $1.9 trillion in assets, a large sum of money, but small in relation to the size of mutual funds ($23 trillion worldwide) and pension funds ($23 trillion worldwide).[1] However, the influence of hedge funds is arguably much larger than the amount of their assets under management due to the leverage employed by most funds, as well as the active nature of many of their trading strategies. For example, one 2009 report cites algorithmic trading (run in large part by hedge funds) as accounting for 73% of all U.S. equity trading volume.[2] Hedge funds also account for a large share of the trading volume across many other financial instruments, such as credit default swaps.

This article is designed to give its readers a firm understanding of the hedge fund industry, their most common investment strategies and the trends shaping the field. In order to accomplish these goals, we need to discuss some background on hedge funds and how they work.

54.2 Hedge Fund Defined

There is no uniformly agreed upon definition of a hedge fund. As with defining risk, the precise definition is in the eye of the beholder. In fact, many hedge funds have no "hedge" at all and choose to increase risk. A common "working" definition of a hedge fund is a private investment vehicle that charges both asset and incentive based fees and is sold to institutional and high net worth investors. This

J.M. Longo (✉)

e-mail: jlongo@business.rutgers.edu

definition would cover the vast majority of funds that hold themselves out to prospective investors as hedge funds. However, it would also encompass most private equity funds and other partnerships.

54.3   History of Hedge Funds

Alfred Winslow (A.W.) Jones is commonly cited as the individual responsible for creating the first hedge fund. His fund commenced in 1949 and lost capital in only 3 of the 34 years of its operation. There is some debate on the topic of who created the first hedge fund. During a trip that I took with a group of students from Rutgers Business School to meet with Warren Buffett in 2006, he stated his belief that Benjamin Graham started the first hedge fund. Buffett noted that Graham, through his Graham – Newman Partnership, went long as well as short in his portfolio and charged his investors an incentive fee. There were likely other investment partnerships (e.g. commodity pools), in operation before Graham-Newman, but scant evidence exists on the details of their operations or investment strategies.

Mallaby (2010) argues that Jones' fund was likely the first to combine four characteristics that are shared by many hedge fund managers today:

1. A performance or incentive fee of 20%, derived from the same profit sharing amount that Phoenician sea captains took from the bounty of their successful voyages.
2. The conscious avoidance of regulation. As we shall see, the regulatory screws are slowly turning on the hedge fund industry, but they are still regulated much less than other financial service firms.
3. Active short selling, in the context of a dynamic long/short investment strategy.
4. The use of leverage, also on a dynamic basis.

The original A.W. Jones Model may be expressed as follows:

$$\textbf{Net Exposure} \ (\%) = (\$ \ \textbf{Long} - \$ \ \textbf{Short})/\$ \ \textbf{Equity}$$
(54.1)

where:

$ Long $=$ the dollar value of long positions held by the fund
$ Short $=$ the dollar value of short positions held by the fund
$ Equity $=$ the net equity in the fund

If Jones were bullish on the direction of the overall stock market, $Long would exceed $Short and the fund would be considered "net long." If he were bearish, the reverse would be true and the fund would be considered "net short.' If the sum of $Long and $Short, known as "gross exposure", was greater than $Equity, then the fund would be leveraged. The earliest hedge fund managers varied each of the elements of the Jones model based on their investment outlooks.

For example, if a fund has $100 million in capital and controls $200 million in long positions and $50 million in short positions, the fund would have a gross exposure of $250 million and net exposure of $150 million in dollar terms, or 150 in percentage terms.

54.4   Notable Hedge Fund Managers

The pioneering hedge funds of Jones, and likely Graham, paved the way for many other hedge fund managers who went on to earn incredible fortunes. Others, such as the partners of Long Term Capital and Bernard Madoff were noteworthy for more infamous reasons. Below is a small sampling of some of the most widely discussed hedge fund managers over the past 20 years.

Arguably, the most famous hedge fund manager is George Soros. He became known as "The man who broke the Bank of England," after his fund, The Quantum Fund, reportedly made a billion dollars in 1 day (September 16, 1992) shorting the British Pound prior to its withdrawal from the European Exchange Rate Mechanism (ERM). Soros himself soon became a billionaire, earning compensation the likes that no one had ever witnessed in the financial services field, except for perhaps Michael Milken in his peak earning years, prior to his downfall.

John Meriwether was the Managing Partner of Long-Term Capital Management, once considered the "Dream Team" of hedge fund managers. Its partners not only included Meriwether and many of his former trading colleagues at Salomon Brothers, but also Nobel Laureates (Myron Scholes and Robert Merton) and the former Vice Chairman of The Federal Reserve (David Mullins). Long Term Capital generated returns of approximately 40% per year from its 1994 launch until its downfall that began in the middle of 1998, triggered by Russia's default on its sovereign debt. The fund at one point controlled $100 billion in assets through an enormous and unintended leverage ratio of 250 to 1.[3] The Federal Reserve organized a bailout of Long Term Capital by a consortium of Wall Street firms in order to avoid the risk of the implosion of the world financial system.

James Simons is the manager of perhaps the most successful hedge fund ever, the Renaissance Medallion Fund. A *Wall Street Journal* article by Patterson and Strasburg (2010) estimates that Medallion has averaged 45% *annually* since its 1988 inception.[4] Simons and his firm, Renaissance Technologies LLC, relies heavily on mathematical models to trade a range of financial securities, including commodities, currencies, and equities.

John Paulson is a hedge fund manager who was the subject of Gregory Zuckerman's book (2010), *The Greatest Trade Ever: The Behind-the-Scenes Story of How John Paulson Defied Wall Street and Made Financial History*. The book details Paulson's shorting of the subprime mortgage market through the use of credit derivatives. According to *Alpha*, a popular hedge fund oriented periodical, Paulson earned $1 billion in 2007, $2 billion in 2008, and $2.3 billion in 2009.

Bernard Madoff is perhaps the most infamous hedge fund manager. Madoff "managed" a series of separate accounts for individuals, institutions, and funds of hedge funds. His "strategy" appeared to generate remarkably consistent returns of 8–12% per annum over a more than two decade period, with very few losses. Of course, it was uncovered that Madoff ran the biggest Ponzi scheme ever, resulting in estimated losses of $18 billion.[4] On June 19, 2009 Madoff was sentenced to 150 years in prison for his crimes. New hedge fund regulations, specified in the Dodd-Frank Act of 2010, are in partial response to the Madoff fraud.

54.5 Growth of the Hedge Fund Industry and Hedge Fund Performance

Hedge funds were somewhat of a sleepy cottage industry until a (Loomis, 1966) *Fortune* article, entitled "The Jones Nobody Keeps Up With," about A.W. Jones. The article noted the outstanding performance of Jones' fund. It increased 670% over the 10-year period ending May 1965. In contrast, the best performing mutual fund over the same time period, Dreyfus Fund, increased 358%. A spawn of imitators soon followed.

The enormous compensation earned by the managers of the most successful hedge funds did not go unnoticed on Wall Street. As we noted earlier, George Soros' Quantum Fund reportedly made a billion dollars in a single day in 1992. His firm's cut was likely 20% of the bounty. Star traders and portfolio managers realized they could earn much more money running their own hedge funds than in almost any other profession *and* operate in an entrepreneurial environment with fewer investment and regulatory constraints.

Another important driving force behind the growth of hedge funds was the influx of institutional money. From the founding of the hedge fund industry in the first half of the twentieth century through the 1980s, high net worth investors comprised the bulk of hedge fund clients. Owning a private hedge fund with limited membership held some cachet in individual social circles. However, over the past decade plus, institutional investors have been responsible for the bulk of incremental hedge fund assets. For example, David Swenson, Chief Investment Officer of Yale's $16 billion endowment, was one of the first institutional

Table 54.1 Hedge fund performance during bear markets

Year	Dow Jones CS HF index (%)	EAFE Int'l index (%)	S&P 500 (%)

2008	−19.10	−39.54	−37.20

Source: Dow Jones Credit Suisse

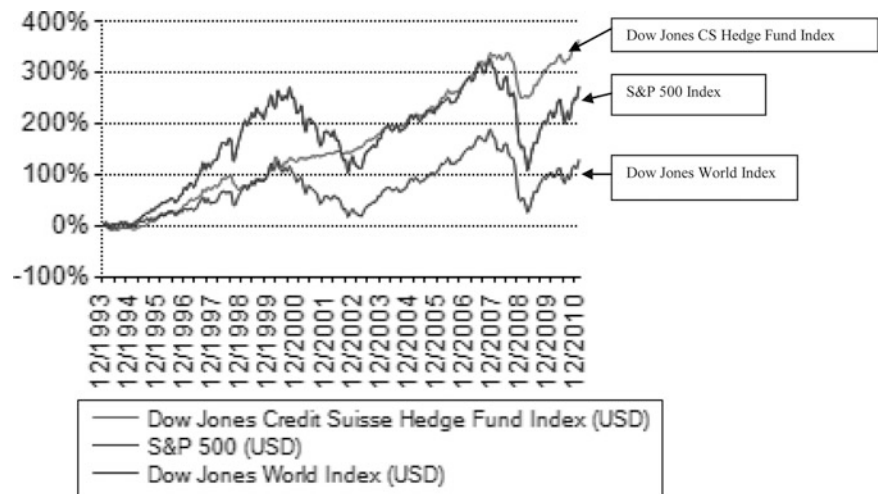
investment managers to allocate a sizeable amount of capital to hedge funds. Many others in the pension and endowment worlds soon thereafter tried to emulate the success of the "Yale Model."

Lastly, hedge funds turned in modest nominal, but strong relative performance during the 2000–2002 bear market in global equities. Their returns in the severe bear market of 2008 were disappointing on a nominal basis, as many hedge funds exhibited no "hedge" at all. Table 54.1 shows the annual returns for these bear market periods for The Dow Jones Credit Suisse Hedge Fund Index, as well as for the S&P 500 and the EAFE Index, a widely cited international equity index.

On the surface historical hedge fund performance has been good, but there are a number of caveats to keep in mind. Most hedge fund databases are rife with a number of biases. Perhaps the two most important are survival bias and backfill bias. Survival bias refers to the likelihood that mostly funds with good performance will report their returns to the database vendors and underperforming funds will decline to report their numbers. This survival bias has the effect of skewing hedge fund databases with winning funds and under-populating them with losing ones. Backfill bias refers to the case where new and successful funds decide to report only after they have developed a successful track record. Of course, new and unsuccessful funds will never report to the hedge fund database vendors. The net result is that some hedge fund databases are "updated" with the strong historical results, thereby resulting in another upward bias to the reported hedge fund returns.

Park et al. (1999) estimate that the various hedge fund biases trim reported hedge fund index returns by approximately 2–3% per annum. There are a number of popular hedge fund databases, including those managed by Pertrac, Hedge Fund Research, Barclays, Dow Jones Credit Suisse, and Morningstar. Prices for hedge fund databases typically range from $1,500 to $10,000 per year.

Notwithstanding the biases noted above, hedge funds in aggregate have demonstrated good historical performance in both nominal and risk adjusted returns, relative to U.S. and global equities. When discussing hedge fund performance it should be noted that hedge funds are far from a

Fig. 54.1 Hedge fund versus equity performance, 1994–2010 (Source: Dow Jones Credit Suisse)


Source: Dow Jones Credit Suisse

Fig. 54.2 Hedge fund performance during equity market drawdowns, 1994–2010 (Source: Dow Jones Credit Suisse)
Source: Dow Jones Credit Suisse

homogeneous asset class. Ideally, a more granular or "apples to apples" comparison should be conducted in order to properly assess the performance of an individual hedge fund. Figure 54.1 illustrates the performance of the Dow Jones Credit Suisse Hedge Fund Index, from its inception in January 1994 through December 2010, as well as for the S&P 500 and Dow Jones World Index over the same period. Hedge funds had a higher return (361.86% total or 9.42% annualized) vs. the S&P 500 (272.10% total or 8.04% annualized) and Dow Jones World Index (128.72% total or 4.99% annualized) and with less risk.

The disappointing hedge fund performance in 2008 resulted in a sharp, but temporary, outflow of assets. Many investors were shocked to find that the hedge funds that they held did not have any hedge at all. The Credit Crisis of 2007–2009 also resulted in a liquidity crunch and the forced deleveraging of many hedge funds. Nevertheless, despite the occasional disappointing absolute returns, the relative

returns of hedge funds have been strong in most down markets. Figure 54.2 show the performance of the Dow Jones Credit Suisse Hedge Fund Index during drawdown periods for the S&P 500. Hedge funds historically have held up very well, notwithstanding the notable 2008 blemish, relative to the S&P 500 and Dow Jones World Index.

In addition to experiencing lower drawdowns relative to most equity indexes, hedge funds historically have also achieved better Sharpe Ratios. Table 54.2 shows that hedge funds historically have more than doubled the Sharpe Ratios of popular equity indexes and provided additional diversification benefits, with approximately 60% correlation to equity indexes. In short, their inclusion in client portfolios will likely result in a better Markowitz Efficient Frontier.

The industry has grown substantially since the days of A. W. Jones. There are approximately 9,237 hedge funds that manage $1.917 trillion in assets at the end of 2010, according to Hedge Fund Research, Inc.[5]

54.6 Common Types of Hedge Funds

Hedge Fund Research, Inc. (HFRI) tracks the performance of more than 100 hedge fund categories, including the 29 shown in Table 54.3.[6] Clearly there is some overlap among the strategies, but the richness of diversity in the universe indicates that it would be a mistake to refer to hedge funds as a homogenous category.

Rather than describe every single hedge fund strategy, our goal here is to discuss some of the most important ones. The biggest slice, some 30% of all hedge fund assets, still resides in the category that Jones pioneered – Equity Long/Short.[7] Additionally, most investors access hedge funds through a fund of funds vehicle, likely because of the "instant diversification" nature of this investment structure. Of course the chief drawback is the second layer of fees that must be paid by investing through the fund of funds vehicle. Fund of funds account for approximately 55% of hedge fund assets.[8] Below we list a brief description of some of the most popular hedge fund strategies.

Activist funds typically purchase a sizeable (i.e. 5% or more) stake in a company and attempt to unlock shareholder value by spurring management or corporate strategy changes. In many respects they operate similar to private equity firms, with the obvious exception that they own a limited amount of shares in publicly traded companies. Carl Icahn was and remains one of the more notable activist investors, who were pejoratively termed "corporate raiders" a couple of decades ago.

Capital Structure Arbitrage is a more generalized version of the convertible bond arbitrage trade and is typically executed through the use of complex derivative instruments, such as a credit default swap. As with most arbitrage trades, either side of the position can be taken, but the typical transaction combination is to be long the bond (through a synthetic position in a credit default swap) and short the common stock. The strategy performs well in most

circumstances, but has difficulty when there is a divergence between stock and bond prices.

Convertible Arbitrage funds typically buy convertible bonds and sell short the common stock of the same company. The hedge fund earns the coupon from the bond and the proceeds from the short sales of the common stock, resulting in a "double carry." The trade is not risk free since dividends may be owed from shorting the common stock and significant losses can be incurred if the bond defaults and the hedge ratio was incorrectly calculated.

Distressed/Credit funds focus on companies that are at risk of default, are in default, or have recently emerged from default. Credit is a more general term for the investment in fixed income securities. For example, credit funds may purchase a pool of loans from an investment bank, such as Citi or Goldman Sachs, at deep discounts. Both distressed and credit strategies place a heavy emphasis on legal work, financial statement analysis and the identification of the "fulcrum" security, or the one that has the maximum voting leverage in the event of a financial reorganization.

Event Driven funds engage in trades based on a specific event such as a merger, special dividend payment, earnings announcement, analyst opinion upgrade, or credit downgrade. Once the event is resolved, favorably or unfavorably, the fund moves on to the next trade.

Fixed Income Arbitrage funds purchase fixed income securities that appear to be undervalued and sell short other fixed income securities, with similar risk, that appear to be overvalued. Leverage is nearly always used to increase both the risk and return of the trade. A common example would be to purchase a basket of government sponsored mortgage backed securities and sell short a portfolio of Treasury securities with a similar duration. The fund captures the spread (since Treasuries always sell at a premium price or lower yield to mortgage backed securities) times the leverage factor, minus the cost of borrowed funds. The trade may backfire during times of market distress, as in the period of The Great Recession.

Global Macro funds generally do not focus on individual securities, but rather emphasize positions in derivatives and index securities on a global basis. They are often unhedged and utilize leverage, making them one of the higher risk hedge fund categories.

Long/Short funds purchase securities perceived to be undervalued while simultaneously selling short those viewed as being overvalued. The long to short, or hedge ratio, variation is based on the manager's outlook. The strategy is typically employed for equity related securities, but is flexible enough to apply to nearly any asset class. The bulk of hedge fund assets are in Long/Short Equity related strategies, making this category the main focus of the examples in this chapter.

Managed Futures funds trade in futures contracts, such as those in commodities, currencies, metals, materials, or index futures. Some analysts call these funds "Commodity Trading Advisors" (CTAs), but the "managed futures" term better signifies the broad array of instruments that these funds may employ.

Market Neutral funds balance the market risk of both the long and short side of the portfolio. A common market neutral example is a long position in Ford and short position in General Motors. The term typically applies to equity oriented funds, but it could also apply to fixed income securities where the duration (i.e. effective maturity) of the fund's long and short positions are balanced.

Merger Arbitrage funds typically purchase a basket of stocks that is the target of a merger or acquisition. The offsetting trade usually involves a short position in the bidding firm. The main risk of the strategy is the loss incurred when a deal falls through, effectively forcing the hedge fund manager to absorb the loss of the takeover premium. Leverage is often utilized to increase both the risk and return of the strategy.

Short Biased funds are either entirely short or have the bulk of their assets sold short. Since the equity and fixed income markets generally trend up over time, few hedge fund managers successfully operate in this category over the long-term. Those that are successful typically focus on small to mid cap firms with company specific problems.

Statistical Arbitrage funds typically employ high frequency computerized trading techniques in order to profit from apparent arbitrage opportunities. True arbitrage opportunities, such as buying IBM in New York and simultaneously shorting it in London for a profit, have no risk and are rare and fleeting if they do exist. The term *statistical* refers to the fact that there may be an arbitrage opportunity according to the fund manager's model; but if the model is not accurate or exogenous factors, such as a takeover occurs, there remains risk in the trade.

Multistrategy funds simultaneously engage in more than one of the previously discussed hedge fund strategies. They attempt to diversify risk by holding a range of strategies and security positions, rather than placing all of their capital in a single approach. For example, a merger arbitrage fund would have difficulty attracting capital in the event of a slow period for deals. Conversely, a multistrategy fund could allocate capital towards those hedge fund categories that appear to have the best chance of prospering in the current market environment.

Fund of Funds purchase positions in a number of individual hedge funds. They attempt to reduce the damage to the portfolio in the event that a specific fund "blows up," such as with Long Term Capital Management. One disadvantage is that their investors incur a second layer of fees, typically 1% of assets under management and 10% of profits.

54.7 Organization and Regulation of Hedge Funds

Hedge fund organization and regulation differs by country, so we will focus on hedge fund organization and regulation in the United States since it is by far the largest hedge fund market. The Investment Company Act of 1940 provides for certain exemptions that allow hedge funds to avoid much regulation. There is a catch – hedge funds can only be offered to a limited number of affluent individual or institutional investors and they cannot advertise in public. The logic is that if a small group of rich individuals or institutions are hurt, it should not be a major blow to the health of the financial system. In addition, high net worth individual and institutional investors, and their advisors, often have the resources to conduct extensive due diligence prior to their investment in hedge funds.

Early hedge funds were organized under the 3(c)(1) exemption of the Investment Company Act of 1940. The 3(c)(1) funds cannot have more than 100 investors and are typically organized under a limited partnership (LP) or limited liability company (LLC) structure. In the U.S., it is problematic to charge incentive fees to investors unless they are "accredited." Accredited investors, under Rule 215 of the Securities Act of 1933 and Rule 501 of Regulation D, must have a net worth in excess of $1 million, or income greater than $200,000 for the past 2 years, with the expectation of doing so in the future. The income figure is raised to $300,000 for couples. The Dodd Frank Act of 2010 explicitly excludes the investor's home in the $1,000,000 net worth figure for accredited investors.

Many hedge funds have two incarnations of their strategy, an onshore fund and offshore fund. Onshore funds are designed to serve domestic, taxable investors. Offshore funds, frequently domiciled in tax haven countries, serve the needs of foreign investors or tax-exempt domestic investors (e.g. pension funds). To a certain extent, funds could circumvent the 100-person limit by creating new funds with slightly different investing objectives. For example, a hedge fund management firm running a Long/Short domestic equity strategy could create a second fund that is focused on Long/Short equities in a *global* investment universe. Furthermore, many hedge funds employ a "master feeder" structure that enables partnerships that consists of many investors to occupy a single slot in the 3(c)(1) fund. Even with these "workarounds," funds lobbied the SEC for a structure that would enable them to serve more investors.

Section 3(c) 7 of the Investment Company Act of 1996 permits a fund to have up to 500 investors, provided that they are "qualified." Qualified individual investors own at least $5 million in investments, excluding home equity. Qualified institutional investors generally have at least $25 million in net assets. Standard hedge fund terms include a 1-year "lockup" provision, asset based fees of 1–2% per year and incentive fees of 20% per year. However, since hedge funds are private agreements these terms may vary significantly. For example, it is not uncommon for some of the most successful managers to have a lockup provision of 3–5 years and an incentive fee in excess of 30% per year.

Most hedge funds also include a "highwater mark" provision. This provision prevents hedge fund managers from receiving incentive fees if they have previously lost money, until the client is "made whole" with subsequent positive returns. Asset management fees are charged regardless of investment performance. The incentive fees are typically taken annually (e.g. on December 31st), while the asset management fees are usually taken near the end of each calendar quarter.

Investment managers, including hedge funds which control more than $100 million in assets, are required to file Form 13F on a quarterly basis with the SEC. Form 13F lists the long equity and option holdings of a fund. Interestingly, short sale positions are not required to be disclosed, as well as more "exotic" holdings of a fund, such as credit default swaps. As we shall discuss later, this "piecemeal" disclosure policy is likely to change. The Dodd Frank Act of 2010 ("Dodd Frank") has brought hedge funds under the "too big to fail" umbrella, so large funds will now be under the purveyance of The Federal Reserve. The SEC has proposed Regulation Private Fund ("Reg PF") to be part of the implementation of Dodd Frank. Reg PF, if approved, would require complete position disclosure of hedge funds, with the information available only to the government on a confidential basis. In addition, nearly all hedge funds will be required to register as investment advisors, making them subject to additional paperwork and inspections. Generally, funds managing $25 million in the U.S. will have to register with the state of their principal office. Once the fund passes the $100 million threshold, it will be required to register at the federal level with the SEC.

54.8 Sample Hedge Fund Strategies

There are virtually an unlimited number of hedge fund strategies ranging from simple long only equity or fixed income holdings to exotic, custom tailored derivative trades. Our focus here is to discuss a few strategies that are common in the hedge fund world, yet also provide insight into how hedge funds view risk and return. We will work through three sample trades, or brief case studies.

54.8.1 Case 1: Dual Share Class Arbitrage

Arbitrage is a common hedge fund strategy, in its multitude of forms. All arbitrage trades, in essence, identify two

Fig. 54.3 Dual share class price differences for Lennar Corporation
securities or portfolios with similar risk characteristics, but with different expected returns. Arbitrage trades involve purchasing the security or portfolio with the high expected return and shorting the corresponding investment(s) with the low expected return. Leverage is often used to increase the risk and return of the trade. A "carry trade" can also be utilized to further increase the risk and expected return of the trade. A carry trade involves borrowing money where it is cheap (e.g. Japan) and investing it in currencies or investments with higher yields.

A relatively "pure" type of arbitrage trade can be found in the analysis of equities with dual shares classes. In this instance, these securities represent two share classes of the same firm that differ in their voting rights, but provide identical claim to earnings and dividends. Dozens of these security pairs exist on American stock exchanges. A combination of liquidity and voting rights helps determine the structural relationship between the two share classes.

For example, the American homebuilding company, Lennar Corporation, has dual share classes. Class B shares have eight times the voting rights of Class A shares, but equal cash flow rights. Figure 54.3 illustrates that Class B shares consistently sell at a *discount* to their Class A counterparts, despite their superior voting rights and identical cash flow characteristics. Over the past 2 years the discount has averaged nearly 22% and ballooned further over the course of the 2007–2009 bear market. The mystery of the large price differentials is cleared up when the trading volume of each share class is analyzed. Class A shares of Lennar have an average trading volume of approximately 4.9 million shares per day, while Class B shares average only 32,000 shares per day. Large institutions are, for most practical purposes, limited to trading in the more liquid Class A shares of Lennar.

A hedge fund manager may put on a trade going long the B share class of Lennar while shorting its A share class. If the spread approaches its historical value of roughly 10% then the trade will earn very attractive returns for the hedge fund manager. Of course, the trade could go against the manager, as occurred in the fall of 2008, if the spread were to widen.

54.8.2 Case 2: Pairs Trading with PetroChina and China National Offshore Oil Corp

Pairs trading is a form of statistical arbitrage that attempts to identify mispricing between two securities. The term "statistical" refers to the likelihood that there is an apparent arbitrage opportunity, but it is not guaranteed. The pairs, sometimes called twins, are usually equities of firms in the same industry, with similar market capitalization, liquidity, and other fundamental attributes. In our example, we will focus on PetroChina (PTR) and China National Offshore Oil Corporation (CEO). Both firms are large capitalization, state owned Chinese energy companies.

The trade often begins by computing the historical ratio of split adjusted prices between two comparable firms. Some analysts prefer to track the historical ratio of a valuation metric, such as Price to Earnings or Enterprise Value to EBITDA, in place of the price ratio. It is common to utilize either 1 year of daily data or 5 years of monthly data to estimate the historical relationship.

In our PTR and CEO example, PTR's price historically averaged 1.27 times the daily, split adjusted price of CEO. The standard deviation of this price ratio was 0.089. Assuming a normal distribution, a 95% confidence interval would entail a high ratio of 1.45 (= 1.27 + 2 * 0.089) and a low ratio of 1.093 (= 1.27 − 2 * 0.089). So, 95% of the time there would be *no trade,* since the price ratio would fall within this boundary. If the ratio of the prices is greater than 1.45 then the hedge fund manager would go long CEO and short PTR. Conversely, if the ratio of the prices were to fall below 1.093 then the manager would go long PTR and short CEO. The manager would close out the trade if the ratio reverted towards its mean of 1.27. If the spread widened, the hedge fund manager would lose money on the trade. Figure 54.4 shows the historical spread of the price ratio between PTR and CEO.

Looking at Figure 54.4 we can see that a trade (Long CEO, Short PTR) would have occurred in early December 2006, since it surpassed the 1.45 upper barrier. Initially the trade would be going against the hedge fund manager, since

Fig. 54.4 Graph of historical price ratio of PetroChina and China National Oil
the ratio continued to increase, peaking in excess of 1.5 at the end of December 2006. However, by April of 2007 the ratio reverted close to its norm of 1.27. Presumably, the manager would have closed out the trade somewhere in this time frame. The manager may have initiated the reverse trade (Long PTR, short CEO) in September of 2007. This trade would also have initially gone against the manager with the ratio continuing to fall to the 1.0 range, until reversing course by October 2007.

Pairs trading relies heavily on the concept of reversion to the mean. If the fundamentals of either company have materially changed, then the historical relationship will likely be of little value in predicting future returns. For example, Ford vs. General Motors (GM) is often cited as a common pairs trade, but their fundamentals vastly diverged in 2009 with GM filing for bankruptcy, while Ford continued to gain market share and have its share price rise.

54.8.3 Case 3: Activist Investor Edward Lampert's Merger of Sears and K-Mart

The first two cases involved the common arbitrage technique of going long one security and short another. Some hedge funds are primarily long only, including the "activist" hedge funds run by legendary investors Edward Lampert and Carl Icahn. During our earlier discussion of activist hedge funds we noted they often take a material position in a company and try to spur meaningful changes, such as a merger, spinoff, or special dividend.

The merger of Sears and K-Mart provides a nice example of what a powerful activist investor may accomplish. Edward Lampert is among the most successful hedge fund managers in history. He has been often compared to Warren Buffett, since they are both value oriented investors with long term investment horizons. Lampert, through his hedge fund, ESL Investments, became the largest shareholder of K-Mart and later a large shareholder of Sears. He strongly encouraged the firms to merge. A deal was announced on

November 17, 2004 and subsequently closed on March 25, 2005. Due to Lampert's sizeable stake in the combined company he was able to appoint himself both Chairman and CEO of the new Sears Holdings Corporation. Lampert said, "In a control position, our ability to create value goes up exponentially."[9] Many activist hedge fund managers have a similar viewpoint. Activist hedge fund often concentrate their positions to have a material stake in their target firms and have a holding period of months to years.

54.9   Trends in Hedge Funds

The hedge fund industry is continuing to evolve. Despite its origins in the early part of the twentieth century, the industry started to "come of age" in the 1990s.[10] Accordingly, it is still young, relative to most other financial service industries. The turbulent financial markets over the past decade have accelerated the rate of change in the industry. Listed below are five trends that will, in my view, affect the hedge fund industry.

54.9.1 Trend 1: Lower Fees

The standard hedge fund fee structure consists of a 1–2% asset based fee and a 20% profit participation or incentive fee. Many funds charge much higher rates and hedge fund of funds charge an additional layer of fees. For example, the financial press routinely reports that SAC Capital's Multistrategy Fund charges a 50% incentive fee (with no asset based fee) and that Renaissance's Medallion Fund charges a fee equal to 5% of assets and 44% of profits. The typical Fund of Fund charges 1% of assets and 10% of profits.

Table 54.4 shows the gross return, typical fees, and net return for a hypothetical fund of fund. For example, a gross return of 10% shrinks to a *net* return of only 4.5% for the investor – pretax! Hedge fund investors were glad to pay

Table 54.4 Gross and net returns for a hypothetical fund of fund

Traditional fund of funds		
Hypothetical gross return		*10.00%*
Less		
Hedge fund – base fee	(1.00%)	
		9.00%
Hedge fund – expenses	(0.65%)	
		8.35%
Hedge fund – incentive fee (20%)	(1.67%)	
		6.68%
Fund of fund – base fee	(1.00%)	
		5.68%
Fund of fund – expenses	(0.65%)	
		5.03%
Fund of fund – incentive fee (10%)	(0.50%)	
Net return to investor		**4.53%**

fees when returns were high, or even just modestly positive in the devastating 2000–2002 bear market. However, in a muddled market environment, these fees will simply generate too great a drag on, and become too large a percentage of, the total fund returns. In contrast, many index mutual funds and exchange traded funds (ETFs) charge fees of 0.25% or less per annum. Actively managed mutual funds charge fees usually in the range of 0.5–1.5%.

In addition, given the proliferation of new managers entering the hedge fund space and the increased competition that will ensue, it is inevitable that the average hedge fund fee will have to come down. Since institutional investors, who have more buying leverage and are not accustomed to paying "rack" retail rates, are contributing to hedge funds, it is hard to imagine that they will not demand fee concessions from many hedge funds in return for large capital commitments. While established "star" managers may be immune from this fee pressure, it is all but certain that emerging managers will have to succumb to fee compression; thereby creating a trend toward a new and lower fee structure which those who follow will have to comply with. This was the trend in the "long only" institutional money management business, which saw fees decline precipitously over the past 20 years due to increased competition and consolidation. This was also the trend in the mutual fund business where high loads and high internal fees were the norm only 10 years ago. The hedge fund business will follow this trend as it matures. It is not a question of "if" but "when" and "by how much?"

54.9.2 Trend 2: Increased Liquidity

Some private investment funds, such as those making venture capital investments in developmental stage firms, have a clear and valid need for long-term lockup arrangements. These funds have returns that typically exhibit a "J Curve" effect where returns are negative in early years as capital is put to work, but strongly positive in later years as the investments are harvested. However, most hedge funds have a 1-year lockup provision and advance notice of 90 days prior to any capital withdrawal. Yet, the underlying instruments in most hedge funds are sufficient for 30 day or less liquidity. Other than the desire to earn fees for a longer period of time, it is hard for the average hedge fund to argue that it is absolutely necessary to hold client funds beyond 30 days.

All else being equal, from the investor's perspective, one does not want to be a year away from accessing their money. The investor wants to be able to withdraw their money in the event that they see something with the fund they do not like, or simply if they need the liquidity. Since most hedge funds do not "need" to have these lock up provisions, as the industry matures, this will be one easy way for managers to distinguish themselves and accommodate client needs. For example, Société Générale's Lyxor alternative investment platform provides access to hedge funds with attractive liquidity terms and factor level transparency. Thus, we see increased liquidity becoming the norm of hedge fund investing, not the exception.

54.9.3 Trend 3: Increased Transparency and Growth of Managed Account Hedge Funds

Investing on faith was once accepted as part of the "price of admission" into the hedge fund industry. Indeed, the cachet of an exclusive or closely guarded strategy may have been a positive attribute for some investors. Then came Long-Term Capital Management and the fraud of Bernard Madoff, both of which were discussed earlier. Factor level transparency may not meet the due diligence requirements of many sophisticated retail or institutional investors. Investors have a right to know exactly what they own and how returns are generated. More investors will make these demands on their hedge fund managers in the face of misleading, and in some cases, fraudulent activity. As such, many funds, especially those newer emerging funds, will be forced to deliver full transparency if they wish to raise substantial assets.

Institutional investors often demand that their hedge fund investments be located in a managed account vehicle (that by definition offers complete transparency and greatly reduced fraud risk) run pari passu with the hedge fund company's traditional partnership structure. To preserve strategy confidentiality, non-disclosure agreements with "teeth" may have to be signed and enforced in return for transparency.

As discussed earlier, hedge funds managing more than $100 million must list their long equity and option holdings on a quarterly basis via Form 13 F. The Dodd Frank Act of 2010 (discussed below) may require registration for funds as small as $25 million. Data reported to the SEC, such as through Form 13F, may be of significant value for deciphering the strategy of longer-term equity oriented hedge funds. However, for active hedge fund mangers the stale data may give some insight into the strategy, but little comfort with respect to a fund's current holdings. In addition, the 13F data do not adequately enable investors to get a good understanding of funds trading in swaps and other complex securities. Short sellers have come under pressure in light of the dramatic drops in shares of financial companies in 2008. In my view, manager short and derivative positions will eventually be required to be disclosed in Form 13F or through some new regulation, such as Regulation PF.

54.9.4 Trend 4: Continued Growth in Hedge Funds

Hedge funds are likely to continue to experience attractive growth for a number of reasons. First, their risk adjusted returns have been reasonably attractive and the moderate correlation that they exhibit with other asset classes may improve the efficient frontier of client portfolios. Second, the Dodd Frank Act of 2010 limits the amount of proprietary trading that banks can conduct, due to the so-called "Volker Rule." The Rule limits proprietary investments to 3% of the firm's primary—or Tier 1—capital. For example, Goldman Sachs has shuttled its equity proprietary trading unit.[11] Morgan Stanley is also scheduled to spin off its Process Driven Trading (PDT) division, historically a leading force behind its equity proprietary trading profits.[12] The natural landing spots for talented prop traders are in hedge funds.

The rise in affluence around the world, most notably in the emerging market "BRIC" countries – Brazil Russia India China – will result in increased demand for hedge funds. Not only will hedge funds be created in these emerging markets, but their high net worth investors will demand that hedge funds manage a portion of their substantial wealth. A portfolio of simply "long only" investments can result in a helpless, sinking feeling during markets such as 2008. Emerging stock markets, such as those in Russia and China, fell in excess of 50% in 2008. Clearly, affluent investors and institutions in these countries would like to temper this volatility and hedge funds are a natural outlet for some of their capital. Lastly, the lure of high compensation will ensure that hedge funds always remain a preferred destination for the proverbial "best and brightest."

54.9.5 Trend 5: Increased Regulation

One of the primary objectives of A.W. Jones' hedge fund was to consciously avoid regulation. The industry has historically escaped significant regulation, but its growth and a number of scandals over the years have made increased regulation inevitable. The Madoff fraud scandal was a particularly embarrassing moment for the SEC, given its numerous forewarnings. It should be noted that unlike the "who's who" of Wall Street firms that needed government bailouts, hedge funds navigated the 2007–2009 Credit Crisis without government assistance.

The Dodd-Frank Act of 2010 represents an important piece of legislation that will result in the regulation of hedge funds. Large hedge funds will fall under the "too big too fail" portion of the Act. As noted earlier, all hedge funds of $100 million or more will have to register with the SEC, while funds of $25 million in size or more, will have to register with states. It is likely that in the not too distant future hedge funds will have to disclose *all* investment positions on a quarterly basis, in a similar manner to mutual funds. Regulation is also likely to increase on a global basis, reducing the opportunity for regulatory arbitrage. In any event, the new regulations that hedge funds will face are less stringent than those faced by firms in other financial industries, such as Insurance, and will likely not materially impede their continued growth.

Conclusion

The term hedge fund is hard to precisely define, given the multitude of strategies, risk management processes and leverage employed by each fund. Nevertheless, hedge funds in their various forms may play a useful role in most individual and institutional portfolio due to the prospect of higher risk adjusted returns, as well as the lack of correlation with traditional stock and bond portfolios. In short, they may improve the Markowitz Efficient Frontier of most portfolios. The industry is still evolving and its continued growth will likely result in the compression of fees, increased liquidity, improved transparency, and increased regulation.

An Appraisal of Modeling Dimensions for Performance Appraisal of Global Mutual Funds

55

G.V. Satya Sekhar

Abstract

A number of studies have been conducted to examine investment performance of mutual funds of the developed capital markets. Grinblatt and Titman (1989, 1994) found that small mutual funds perform better than large ones and that performance is negatively correlated to management fees, but not to fund size or expenses. Hendricks, Patel, and Zeckhauser (1993), Goetzmann and Ibbotson (1994), and Brown and Goetzmann (1995) present evidence of persistence in mutual fund performance. Grinblatt and Titman (1992), and Elton et al. (Journal of Financial Economics 42:397–421, 1996) show that past performance is a good predictor of future performance. Blake, Elton, and Grubber (1993), Detzler (1999), and Philpot, Hearth, Rimbey, and Schulman (1998) find that performance is negatively correlated to fund expense, and that past performance does not predict future performance. However, Philpot, Hearth, and Rimbey (2000) provide evidence of short-term performance persistence in high-yield bond mutual funds. In their studies of money market mutual funds, Domian and Reichenstein (1998) find that the expense ratio is the most important factor in explaining net return differences. Christoffersen (2001) shows that fee waivers matter to performance. Smith and Tito (1969) conducted a study into 38 funds for 1958–67 and obtained similar results. Treyner (Harvard Business Review 43:63–75, 1965) advocated the use of Beta Coefficient instead of the total risk.

Statistical Technique used: This paper is intended examine the modeling dimensions of measuring performance of mutual funds during the last 50 years, which leads to innovative research in financial modeling of mutual fund's performance measure with the help of various models like: regression model, Treynor Model, Lee Model etc..

Objectives

1. To understand financial modeling techniques used for performance evaluation of global mutual funds during last 50 years.
2. To develop scope for new model in the area of performance appraisal of mutual funds

Keywords

Financial modeling • Global investments • Mutual funds • Performance appraisal

55.1 Introduction

The measure of performance of financial instruments is basically dependent three important models derived independently by Sharpe, Jensen and Treynor. All three models are based on the assumption that (1) all investors are averse

G.V. Satya Sekhar (✉)
Gandhi Institute of Technology and Management Studies,
GITAM, University, Visakhapatnam, India
e-mail: gudimetlavss@yahoo.com

to risk, and are single period expected utility of terminal wealth maximizers, (2) all investors have identical decision horizons and homogeneous expectations regarding investment opportunities, (3) all investors are able to choose among portfolios solely on the basis of expected returns and variance of returns, (4) all trans-actions costs and taxes are zero, and (5) all assets are infinitely divisible.

55.2 Performance Evaluation Methods

The following paragraphs indicate a brief description of the studies on 'performance evaluation of mutual funds'.

Friend et al. (1962)[1] offered the first empirical analysis of mutual funds performance. Sharpe (1964), Treynor and Mazuy (1966), Jensen (1968), Fama (1972), Grinblatt and Titman (1989, 1994) are considered to be classical studies in performance evaluation methods. Sharpe (1964)[2] made a significant contribution in the methods of evaluating mutual funds. His measure is based on capital asset prices, market conditions with the help of risk and return probabilities. Sharpe (1966) developed a theoretical measure better known as reward to variability ratio that considers both average return and risk simultaneously in its ambit. It tested efficacy through a sample of 34 open-ended funds considering annual returns and standard deviation of annual return risk surrogate for the period for 1954–1963. The average reward to variability ratio of 34 funds was considerably smaller than Dow Jones portfolio, and considered enough to conclude that average mutual funds performance was distinctly inferior to an investment in Dow Jones Portfolio.[3]

Treynor (1965)[4] advocated the use of Beta Coefficient instead of the total risk. He argues that using only naïve diversification, the unsystematic variability of returns of returns of the individual assets in a port folio typically average out of zero. So he considers measuring a portfolio's return relative to its systematic risk more appropriate.

Teynor and Mazuy (1966)[5] devised a test of ability of the investment managers to anticipate market movements. The study used the investment performance outcomes of 57 investment managers to find out evidence of market timing abilities and found no statistical evidence that the investment managers of any of the sample funds had successfully outguessed the market. The study exhibited that the investment managers had no ability to outguess the market as a whole but they could identify under priced securities.

Michael C. Jensen (1967)[6] conducted an empirical study of mutual funds during the period 1954–64 for 115 mutual funds. His results indicate that these funds are not able to predict security prices well enough to outperform a buy-the-market and hold policy. His study ignores the gross management expenses to be free. There was very little evidence that any individual fund was able to do significantly better than which investors expected from mere random chance. Jensen (1968) measured the performance as the return in excess of equilibrium return mandated by Capital Asset Pricing Model. Jensen's measure is based on the theory of the pricing of capital assets by Sharpe (1964) Lintner (1965) and Teynor.

Smith and Tito (1969)[7] conducted a study into 38 funds for 1958–67 and published results relating to performance of mutual funds. However, Mc Donald (1974) examined 123 mutual funds for 1960–69 measures to be closely correlated more importantly, he found that on an average, mutual funds perform about as well as native 'Buy and Hold' strategy.

Fama (1972)[8] suggested alternative methods for evaluating investment performance with somewhat finer breakdowns of performance on the stock selection, market timing, diversification and risk bearing. It devised mechanism for segregation part of an observed investment return due to managers' ability to pick up the best securities at a given level of risk from part that is due to the prediction of general market price movements.

Dunn and Theisen (1983)[9] study is about ranking by the annual performance of 201 institutional portfolios for the period 1973 through 1982 without controlling for fund risk. They found no evidence that funds performed within the same quartile over the 10-year period. They also found that ranks of individual managers based on 5-year compound returns revealed no consistency.

Eun et al. (1991)[10] reported similar findings. The benchmarks used in their study were the Standard and Poor's 500 Index, the Morgan Stanley Capital International World Index, and a self-constructed index of U.S. multinational firms. For the period 1977–1986, the majority of international funds outperformed the U. S. market. However, they are most failed to outperform the world index. The sample consisted of 19 U. S.-based international funds, and the Sharpe measure was used to assess excess returns.

Barua and Varma (1993b)[11] have examined the relationship between the NAV and the market price on

Mastershares. They conclude that market prices are far more volatile than what can be justified by volatility of NAVs. The prices also show a mean reverting behaviour, thus perhaps providing an opportunity for discovering a trading rule to make abnormal profits in the market. Such a rule would basically imply buying Mastershares whenever the discount from NAV was quite high and selling Mastershares whenever the discount was low.

Droms and Walker (1994)[12] used a cross-sectional/time series regression methodology. Four funds were examined over 20 years (1971–1990), and 30 funds were analyzed for a 6-year period (1985–1990). The funds were compared to the Standard and Poor's 500 Index, the Morgan Stanley Europe, Australia, and Far East Index (EAFE) which proxies non-U. S. stock markets, and the World Index. Applying the Jensen, Sharpe, and Treynor indices of performance, they found that international funds have generally underperformed the U. S. market and the international market. Additionally, their results indicated that portfolio turnover, expense ratios, asset size, load status and fund size are unrelated to fund performance.

Bauman and Miller (1995)[13] studied the persistence of pension and investment fund performance by type of investment organization and investment style. They employed a quartile ranking technique because they noted that "investors pay particular attention to consultants' and financial periodicals' investment performance rankings of mutual funds and pension funds". They found that portfolios managed by investment advisors showed more consistent performance (measured by quartile rankings) over market cycles and that funds managed by banks and insurance companies showed the least consistency. They suggest that this result may be caused by a higher turnover in the decision-making structure in these less consistent funds. This study controls for the effects of turnover of key decision makers by restricting the sample to those funds with the same manager for the entire period of study.

Volkman and Wohar (1995)[14] extend this analysis to examine factors that impact performance persistence. Their data consists of 322 funds over the period 1980–1989, and shows performance persistence is negatively related to size and negatively related to levels of management fees.

Elton et al. (1996)[15] examined the predictability of stock mutual funds performance based on risk-adjusted future performance. It also demonstrated application of modern portfolio techniques on past data to improve selection, which permitted construction of portfolio funds that significantly outperformed a rule based on the past rank alone. The portfolio so selected was reported to have small, but statistically significant, positive risk-adjusted returns during a period when mutual funds in general had negative risk adjusted returns.

Jayadev (1996)[16] paper enlightens performance evaluation based on monthly returns. His paper focuses on performance of two growth oriented mutual funds (Mastergain and Magnum Express) on the basis of monthly returns compared to benchmark returns. For this purpose, risk adjusted performance measures suggested by Jensen and Treynor and Sharpe are employed.

Carhart (1997)[17] shows that expenses and common factors in stock returns such as beta, market capitalization, 1-year return momentum, and whether the portfolio is value or growth oriented "almost completely" explain short term persistence in risk-adjusted returns. He concludes that his evidence does not "support the existence of skilled or informed mutual fund portfolio managers".

Yuxing yan (1999)[18] examined performance of 67 US mutual funds and the S &P 500 index with 10-year daily return data from 1982 to 1992. The S & P index was used as bench mark index. Daily data are transformed into weekly data for computational reasons. In the calculations, it was assumed that the S & P 500 market index is a good one, i.e., it is efficient and its variance is constant.

Arnold et al. (2000)[19] study examines the risk-adjusted returns using Sharpe's Index, Treynor's Index and Jensen's Alpha for five portfolios of international mutual funds during 1985–1994. The bench marks for competition were the U.S. market proxied by the Vanguard Index 500 mutual fund and a portfolio of funds that invest solely in U.S. stocks. The results show that for 1985 through 1994 the portfolio of international mutual funds outperformed the U.S. market and the portfolio of U.S mutual funds.

Rahul Bhargava et al. (2001)[20] evaluated the performance of 114 international equity managers over the January 1988 to December, 1997 period. Performance tests are conducted using Sharpe, Jensen performance methodologies. Three major findings are reported. First, international equity managers, on an average, were unable to outperform the MSCI world market proxy during the sample period. Second, geographic asset allocation and equity style allocation decisions enhanced the performance of international managers during the sample period. Third, separately managed funds were outperformed mutual funds.

Sadhak (2003)[21] study is an attempt to evaluate the performance of Indian mutual funds with the help of data pertaining to: (a) trends in income and expenses, (b) investment yield and risk-associated returns, and (c) returns of Indian mutual funds vis-à-vis returns of other emerging markets.

Bala Ramasamy and Yeung's (2003)[22] survey focused on Malaysia where the mutual fund industry started in the 1950s but only gained importance in 1980s with the establishment of government initiated programme. The sample size consisting of 56 financial advisors representing various life insurance and mutual fund companies resulted in 864 different profiles of mutual funds. The cojoint analysis was employed to generate the questionnaire and analyse its results. The results of this survey point to three important factors which dominate the choice of mutual funds. These are consistent past performance, size of funds and costs of transaction.

Chang et al. (2003),[23] identified hedging factor in the equilibrium asset pricing model and use this benchmark to construct a new performance measure. Based on this measure, they are able to evaluate mutual fund managers hedging timing ability in addition to more traditional security selectivity and timing. While security selectivity performance involves forecasts of price movements of selected individual stock, market timing measures the forecasts of next period realizations of the market portfolio. The empirical evidence indicates that the selectivity measure is positive on average and the market timing measure is negative on average.

Alexander (2004)[24] has suggested a new dimension called 'modified approach for risk-adjusted performance of mutual funds'. This method can be considered as more powerful, because it allows not only for an identification of active resources, but also for identification of risk. He observed two interesting results: First, it can be shown that in some cases, a superior security selection effect is largely dependent on taking higher risks. Second, even in the small sample analyzed in the study, significant differences appear between each portfolio manager's styles of selection.

Gupta OP and Amitab Gupta (2004)[25] published their research on select Indian mutual funds during 4 year period from 1999 to 2003 using weekly returns based on NAVs for 57 funds. They found that fund managers have not outperformed the relevant benchmark during the study period. The funds earned an average return of 0.041 per week against the average market return of 0.035%. The average risk free rate was 0.15% per week indicating that the sample funds have not earned even equivalent to risk-free return during the study period.

Subash Chander and Jaspal Singh (2004)[26] considered selected funds during the period Nov 1993 to March, 2003 for the purpose of their study. It was found that Alliance Mutual Fund and Prudential ICICI Mutual funds have posted better performance for the period of study in that order as compared to other funds. Pioneer ITI, however, shown average performance and Tepleton India mutual fund has staged a poor show.

Amit Singh Sisodiya (2004)[27] makes comparative analysis of performance of different mutual funds. He explains that, a fund's performance when viewed on the basis of returns alone would not give a true picture about the risk the fund would have taken. Hence, a comparison of risk-adjusted return is the criteria for analysis.

Alberto et al. (2005)[28] analyzed the passive role that, implicitly, would place institutional investors in such a context. The study was conducted in Italy using empirical evidence form the Italian stock exchange (Comit Index). This study finds that three factors reduce the freedom of institutional investors to manage their portfolio- the market target size, the fund structure and the bench marking.

Sudhakar and Sasi Kumar (2005)[29] made a case study of Franklin Templeton mutual fund. The sample consists of a total 10 growth oriented mutual funds during the period April 2004 to March 2005. NIFTY based on NSE Index was used as the proxy for the market index and each scheme is evaluated with respect to the NSE index to find out whether the schemes were able to beat the market or not. It was found that most of growth oriented mutual funds have been able to deliver better returns than the benchmark indicators. In the sample study, all the funds have positive differential returns indicating better performance and diversification of the portfolio, except two funds with negative differential returns viz., Franklin India Blue Chip Fund, Templeton India Income Fund.

Martin Eling (2006)[30] made a remarkable contribution to the theory of 'performance evaluation measures'. In this study, data envelopment analysis (DEA) is presented as an alternative method for hedge fund performance measurement. As an optimization result, DEA determines an efficiency score, which can be interpreted as a performance measure. An important result of the empirical study is that

[30] Martin Eling (2006).

completely new rankings of hedge funds compared to classic performance measures.

George Comer (2006)[31] examined the stock market timing ability of two samples of hybrid mutual funds. It was found that the inclusion of bond indices and a bond timing variable in a multifactor Treynor-Mazuy model framework leads to substantially different conclusion concerning the stock market timing performance of these funds relative to the traditional Treynor-Mazuy model find less stock timing ability over the 1981–91 time period provide evidence of significant stock timing ability across the second fund sample during the 1999–2000 period.

Yoon K Choi (2006)[32] proposed an incentive compatible portfolio performance evaluation measure In this model, a risk-averse portfolio manager is delegated to manage a fund, and his portfolio construction (and information-gathering) effort is not directly observable to investors. in which managers are to maximize investors' gross returns net of managerial compensation. He considers the effect of organizational elements such as economics of scale on incentive and thus on performance.

Ramesh Chander (2006),[33] study examined the investment performance of managed portfolios with regard to sustainability of such performance in relation to fund characteristics, parameter stationarity and benchmark consistency. The study under consideration is based on the performance outcome of 80 investment schemes from public as well as private sector for the 5-year period encompassing January 1998 through December 2002. The sample comprised 33.75% of small, 26.75% of medium, 21.25% of large and 18.75 of the giant funds.

Ramesh Chander (2006a)[34] study on market timing abilities enables to understand how well the manager has been able to achieve investment targets and how well risk has been controlled in the process. The results reported were unable to generate adequate statistical evidence in support of manager's successful market timing. It persisted across measurement criteria, fund characteristics, and the bench mark indices. However, absence of performance is noted for alternative sub-periods signifying the negation of survivorship bias.

Beckmann et al. (2007)[35] found that Italian female professionals do not only assess themselves as more risk averse than their male colleagues, they also prefer a more passive portfolio management compared to the level they are allowed to. Besides, in a competitive tournament scenario near the end of the investment period, female asset managers do not try to become the ultimate top performer when they have outperformed the peer group. However in case of underperformance, the risk of deviating from the benchmark makes female professionals more willing than their male colleagues to seize a chance of catching up.

Gajendra Sidana (2007)[36] made an attempt to classify 100 mutual funds employing cluster analysis and using a host of criteria like the 1 year old return, 2 year annualized return, 3 year annualized return, 5 year annualized return, alpha, beta etc. The data is obtained from value-research. The author finds inconsistencies between investment style/objective classification and the return obtained by the fund.

Coates and Hubbard (2007)[37] reviewed the structure, performance and dynamics of the mutual fund industry, and showed that they are consistent with competition. It was also found that concentration and barriers to entry are low, actual entry is common and continuous, pricing exhibits no dominant long-term trend, and market shares fluctuate significantly. Their study also focused on 'effects of competition on fee' and 'pricing anomalies'. They suggested legal interventions are necessary in setting fee in mutual funds of United States.

Subha and Bharathi (2007)[38] study is carried out for open end mutual fund schemes and 51 schemes are selected by convenient sampling method. NAV's are taken for a period of 1 year from 1st October 2004 to 30th September, 2005. Out of the 51 funds as many as 18 schemes earned higher returns than the market return. The remaining 33 funds however generated lower returns than the market.

Sondhi (2007)[39] study analyses the financial performance of 36 diversified equity mutual funds in India, in terms of rates of return, comparison with risk free return, bench mark comparison and risk adjusted returns of diversified equity funds. Fund size, ownership pattern of AMC and type of fund are the main factors considered in this study. The study reveals that private sector is dominating public sector.

Cheng-Ru Wu et al. (2008)[40] study adopts modified Delphi method and the analytical hierarchy process to design an assessment method for evaluating mutual fund performance. The most important criteria of mutual fund performance should be 'mutual fund style' following is 'market investment environment'. This result indicates investor's focus when they evaluate the mutual fund performance.

between years 1997 and 2005. The study evaluated performance of each fund based on the CAPM performance methodology, calculating the Treynor and Sharpe Indexes for the 9 year period as well as for three sub-periods displaying different market characteristics. The results indicated that the majority of the funds under examination followed closely the market, achieved overall satisfactory diversification and some consistently outperformed the market, while the results in market timing are mixed, with most funds displaying negative market timing capabilities.

Kajshmi et al. (2008),[42] studied a sample of schemes in the 8 years period. This study is based on performance evaluation is restricted to the schemes launched in the year 1993 when the industry was thrown open to private sector under the regulated environment by passing the SEBI(Mutual Funds) Regulations 1993. The performance of the sample schemes were in line with that of the market as evident from the positive beta values. All the sample schemes were not well diversified as depicted by the differences in the Jensen alpha and Sharpe's differential return.

Massimo Masa and Lei Zhang (2008)[43] found the importance of organizational structure on Asset Management Company of mutual fund. Their study found that more hierarchical structures invest less in firms located close to them and deliver lower performance. An additional layer in hierarchical structure reduces the average performance by 24 basis points per month. At the same time, more hierarchical structures leads to herd more and to hold less concentrated portfolios.

Manuel Ammann and Michael Verhofen (2008)[44] examined the impact of prior performance on the risk-taking behaviour of mutual fund managers. Their sample taken from US funds starts in Jan 2001 and ends in Dec, 2005. The study found that prior performance in the first half of the year has, in general, a positive impact on the choice of the risk level in the second half of the year. Successful fund managers increase the volatility, the beta, and assign a higher proportion of their portfolio to value stocks, small firms, and momentum stocks in comparison to unsuccessful fund managers.

Onur et al. (2008)[45] study evaluates the performance of 50 large US-based international equity funds using risk-adjusted returns during 1994–2003. This study provides documentation on the risk-adjusted performance of international mutual funds. The evaluation is based on objective performance measures grounded in modern portfolio theory. Using the methodology developed by Modigliani and Miller

in 1997, the study reports the returns that would have accrued to these mutual funds for a 5-year holding period as well as a 10-year holding period. It is evident from the empirical results of this study that the funds with the highest average returns may lose their attractiveness to investors once the degree of risk embedded in the fund has been factored into the analysis.

Qiang Bu and Nelson Lacey (2008)[46] examined the determinants of US mutual fund terminations and provided estimates of mutual fund hazard functions. Their study found that mutual fund termination correlates with a variety of fund specific variables as well as with market variables such as the S&P 500 index and the short-term interest rate. This was tested with the underlying assumptions of the semi-parametric Cox model and reject proportionality. They also found that different fund categories exhibit distinct hazard functions depending on the fund's investment objectives.

Smith (2009)[47] discussed the size and market concentration of the mutual fund industry, the market entry and exit of mutual funds, the benefits and costs of mutual fund size changes, principal benefits and costs of ownership from fund shareholders' perspective etc. This study is based on data from Morningstar (2009) about US mutual fund industry, which was composed of 607 fund families.

Bake et al. (2009)[48] investigated the relation between the performance and characteristics of 118 domestic actively managed institutional equity mutual funds. The results showed that the large funds tend to perform better, which suggests the presence of significant economies of scale. The evidence indicates a positive relation between cash holding and performance. They also found evidence in a univariate analysis that expense ratio class is an important determinant of performance, and the results are significant in a multivariate setting using Miller's active alpha as a performance metric.

Khurshid et al. (2009)[49] studied the structure of the mutual fund industry in India and analyzed the state of competition among all the mutual funds in private sector and public sector. The levels of competition and their trends have been obtained for the periods March 2003 to March, 2009. This study found over-all mutual fund industry is facing a high competitive environment. An increasing trend of competition was observed within Bank-Institution, Private sector foreign and private sector joint venture mutual funds.

Mohit Gupta and Agarwal (2009)[50] study focused on the portfolio creation and industry concentration of 18 ELSS schemes during April 2006 to April 2007. Mutual fund

industry concentration was the variable used in classification or cluster creation. This exercise was repeated each month for the period under study. Finally portfolio performance was compared with index fund, portfolio of three randomly picked funds of the previous month, and the return and risk parameters of ELSS category as a whole.

Amar Ranu and Depali Ranu (2010)[51] critically examined the performance of equity funds and found out the top 10 best performing funds among 256 equity mutual fund schemes in this category. Their considers three criteria for selection: (a) mutual funds having 5 years of historical performance, (b) fund schemes having a minimum of Rs.400 crore of assets under management and (c) fund which have average return more than 22.47. They found that HDFC TOP 200(Growth) option was outperforming among the top 10 best performing equity funds.

Sunil Whal and Albert Wang (2010)[52] found impact of the entry of new mutual funds on incumbents using the overlap in their portfolio holdings as a measure of competitive intensity. Their study reveals that funds with high overlap also experience quantity competition through lower investor flows, have lower alphas, and higher attrition rates. These effects only appear after the late 1990s, at which point there appears to be endogenous structural shift in the competitive environment. Their concluding remark is that 'the mutual fund market has evolved into one that displays the hallmark features of a competitive market'.

55.3 A Review on Various Models for Performance Evaluation

55.3.1 Jensen Model

Given the additional assumption that the capital market is in equilibrium, all three models yield the following expression for the expected one period return on any security (or portfolio) j [53]:

$$E(R_j) = RF + \beta_J[E(R_m) - RF] \quad (55.1)$$

RF = the one-period risk free interest rate.

$\beta_J = cov(j\,R_J, R_M)/\sigma^2\,R_M$ = the measure of risk (hereafter called systematic risk) which the asset pricing model implies is crucial in determining the prices of risky assets.

$E(R_M)$ = the expected one-period return on the "market portfolio" which consists of an investment in each asset in the market in proportion to its fraction of the total value of

all assets in the market. It implies that the expected return on any asset is equal to the risk free rate plus a risk premium given by the product of the systematic risk of the asset and the risk premium on the market portfolio.

55.3.2 Fama Model

In Fama's decomposition performance evaluation measure of portfolio, overall performance can be attributed to selectivity and risk.[54] The performance due to selectivity is decomposed into net selectivity and diversification. The difference between actual return and risk-free return indicates overall performance:

$$Rp - Rf \quad (55.2)$$

Where in

Rp: is actually return on the portfolio, which is monthly average return of fund.

Rf- is monthly average return on treasury bills 91-days.

The overall performance further can be bifurcated into performance due to selectivity and risk

Thus,

$$Rp - Rf = \left[Rp - Rp(\beta_p) + Rp(\beta_p) - Rf\right] \quad (55.3)$$

In other words, Overall performance = selectivity + risk

55.3.3 Treynor and Mazuy Model

Treynor and Mazuy developed a prudent and exclusive model to measure investment managers' market timing abilities.[55] This formulation is obtained by adding squared extra return in the excess return version of the capital asset pricing model as given below:

$$(R_{pt} - R_{ft}) = \alpha + \beta p(R_{mt} - R_{ft}) + yp(R_{mt} - R_{ft})^{2+} e_{pt} \quad (55.4)$$

Where: Rpt – is monthly return on the fund, Rft- is monthly return on 91 days treasury bills, Rmt- is monthly return on market index, Ept is error term

This model involves running a regression with excess investment return as dependent variable and the excess market return and squared excess market return as independent variables. The value of coefficient of squared excess return acts as a measure of market timing abilities that has been

[51] Amar Ranu and Depali Ranu (2010).
[52] Sunil Wahal and Alber (Yan) Wang (2010).
[53] Jensen (1967).
[54] Fama (1972).
[55] Treynor et al. (1966).

tested for significance of using *t*-test. Significant and positive values provide evidence in support of the investment manager's successful market timing abilities.

55.3.4 Statman Model

Statman measured mutual funds using the following equation[56]:

eSDAR (excess standard deviation and adjusted return)

$$= R_f + (R_p - R_f)(Sm/Sp) - Rm \quad (55.5)$$

In this formulae: Rf- monthly return on 3-month treasury bills, Rp – monthly return on fund portfolio

Rm- monthly return on the benchmark index, Sp- standard deviation of portfolio p's return and Sm – standard deviation of return on the bench mark index.

This model used for short-term investment analysis. The performance is compared with it bench mark on monthly basis.

55.3.5 Choi Model

Choi provides a theoretical foundation for an alternative portfolio performance measure that is incentive-compatible.[57] In this model, a risk-averse portfolio manager is delegated to manage a fund, and his portfolio construction (and information-gathering) effort is not directly observable to investors. The fund manager is paid on the basis of the portfolio return that is a function of effort, managerial skill, and organizational factors. In this model, the effect of institutional factors is described by the incentive contractual form and disutility (or cost) function of managerial efforts in fund operations. It focuses on the cost function as an organizational factor (simply, scale factor). It was assumed that the disutility function of each fund is determined by the unique nature of its operation (e.g., fund size) and is an increasing function of managerial effort at an increasing rate.

55.3.6 Elango Model

Elango model is also compares the performance of public sector funds vs private sector mutual funds in India.[58] In order to examine the trend in performance of NAV during the study period, growth rate in NAV was computed. The growth rate was computed based on the following formula:

$$\text{Growth Rate}: Rg = (Y_t - Y_0/Y_0) \times 100 \quad (55.6)$$

Rg : Growth rate registered during the current year
Y_1 : yield in current year
Y_0 : yield in previous year

In order to examine whether past is any indicator of future growth in the NAV six regression analyses were carried out. NAV of base year was considered as the dependent variable and current year as in the independent variable.

$$\text{Equation}: Y = A + bX$$
$$\text{Dependent variable}: Y = NAV \ of \ 1999 - 2000 \quad (55.7)$$
$$\text{Independent variable}: X = NAV \ of \ 2000 - 01$$

In the same way, the second regression equation computed using NAVs of 2000–01 and 2001–02, as dependent and independent variables.

55.3.7 Chang, Hung and Lee Model

The pricing model adopted by Jow-Ran chang, Nao-Wei Hung and Cheng-Few Lee is based on competitive equilibrium version of intemporal asset pricing model derived in Campbell.[59] The dynamic asset pricing model incorporates hedging risk as well as market. This model uses a loglinear approximation to the budget constraint to substitute out consumption from a standard intertemporal asset pricing model. Therefore, asset risk premia are determined by the covariances of asset returns with the market return and with news about the discounted value of all future market returns. Formally, the pricing restrictions on asset *i* imported by the conditional version of the model are:

$$E_t r_{i,t+1} - rf_{,t+1} = -V_{iI}/2 + \gamma V_{im} + (\gamma - 1)V_{ih} \quad (55.8)$$

Where:

Etri, t + 1; log return on asset, *r f,t* + 1 log return on riskless asset, *Vii* denotes Var*t* (*ri,t* + 1), *γ* is the agent's coefficient of relative risk aversion, *Vim* denotes *Covt* (*ri,t* + 1, *rm,t* + 1),   and   *Vih* = *Covt*(*ri, t* + 1, (*Et* + 1 − *Et*), _∞*j* = 1*ρj rm, t* + 1 + *j*), the parameter: $\rho = 1 - \exp(c - w)$ and *c* − *w* is the mean log consumption to wealth ratio.

This states that the expected excess log return in an asset, adjusted for a Jensen's inequality effect, is a weighted average of two covariances: the covariance with the return from the market portfolio and the covariance with news about future returns on invested wealth. The

Table 55.1 Overview of different measures

Measures	Description	Interpretation
Sharpe ratio	Sharpe Ratio = Fund return in excess of risk free return/Standard deviation of Fund. Sharpe ratios are ideal for comparing funds that have a mixed asset classes	The higher the Sharpe ratio, the better a funds returns relative to the amount of risk taken
Treynor ratio	Treynor ratio = Fund return in excess of risk free return/Beta of Fund. Treynor ratio indicates relative measure of market risk	The higher the Treynor ratio shows higher returns and lesser market risk of the fund
Jensen measure	This shows relative ratio between alpha and beta	Jensen measure is based on systematic risk. It is also suitable for evaluating a portfolio's performance in combination with other portfolios
M^2 measure	It matches the risk of the market portfolio and then calculate appropriate return for that portfolio	A high value indicates that the portfolio has outperformed and vice versa
Jensen model	$E(R_j) = RF + \beta_J[E(R_m) - RF]$	The expected one-period return on the "market portfolio" which consists of an investment in each asset in the market in proportion to its fraction of the total value of all assets in the market
Fama model	$Rp - Rf = [Rp - Rp(\beta_{p)} + Rp(\beta_{p)} - Rf)]$	Overall performance = selectivity + risk
Treynor and Mazuy model	$(R_{pt} - R_{ft}) = \alpha + \beta p(R_{mt} - R_{ft}) + yp(R_{mt} - R_{ft})^{2+}e_{pt}$	This model involves running a regression with excess investment return as dependent variable and the excess market return and squared excess market return as independent variables
Statman model	$eSDAR = R_f + (R_p - R_f)(Sm/Sp) - Rm$	This model used for short-term investment analysis. The performance is compared with it bench mark on monthly basis
Elango model	$Rg = (Y_t - Y_0/Y_0)X100$	In order to examine whether past is any indicator of future growth in the NAV six regression analyses were carried out. NAV of base year was considered as the dependent variable and current year as in the independent variable

intuition in this equation that assets are priced using their covariances with the return on invested wealth and future returns on invested wealth.

55.3.8 MM Approach

Leah Modigliani and Franco Modigliani better known as M^2 in the investment literature. This measure is developed adjusting portfolio return.[60] This adjustment is carried on the uncommitted(cash balances) part of the investment portfolio at the risk-less return so as to enable all portfolio holdings to participate in the return generation process. This adjustment is needed to bring out the level playing field for portfolio risk-return and vis-à-vis market return. The effect of this adjustment is reported below:

$$M^2 =^* Rp - Rm \qquad (55.9)$$

$$^*Rp = (Rf \ ^*(1 - Sdm/Sdp)) + (Rp \ ^* Sdm/Sdp) \qquad (55.10)$$

In this formulae: * Rp = expected return, Rf = Risk free return, Sdm = Standard deviation of market portfolio and Sdp = Standard deviation of managed portfolio

In case the managed portfolio has twice the standard deviation of the market, then, the portfolio would be half invested in the managed portfolio and remaining half be invested at the risk-less rate. Like wise, in case the managed portfolio has lower standard deviation than the market portfolio, it would be levered by borrowing money and investing the money in managed portfolio. Positive M^2 value indicate superior portfolio performance while the negative indicates actively managed portfolio manager's inability to beat the benchmark portfolio performance (Table 55.1).

55.4 Conclusion

This paper is intended to examine various performance models derived by financial experts across the globe. A number of studies have been conducted to examine investment performance of mutual funds of the developed capital markets. The measure of performance of financial instruments is basically dependent three important models derived independently by Sharpe, Jensen and Treynor. All three models are based on the assumption that (1) all investors are averse to risk, and are single period expected utility of terminal wealth maximizers, (2) all investors have identical

---

[60] Modigliani et al. (1997).

decision horizons and homogeneous expectations regarding investment opportunities, (3) all investors are able to choose among portfolios solely on the basis of expected returns and variance of returns, (4) all trans-actions costs and taxes are zero, and (5) all assets are infinitely divisible.

Abstract

This chapter reviews structural credit risk models. Special emphasis is on the distinction between endogenous default versus exogenous default and the economic implications of the different assumptions. It is argued that models with endogenous default provide more insight into the default process. On the other hand, assuming exogenous default gives the flexibility to include certain features that are observed in actual credit markets.

56.1 Introduction

This chapter surveys the literature on structural credit risk models with emphasis on the distinction between models with endogenous default versus those with exogenous default. It is argued that models with exogenous default may be internally inconsistent and even biased. With exogenous default an arbitrary default barrier is assumed and, therefore, default probabilities can be manipulated by modifying the assumptions related the barrier. These types of problems, although not entirely eliminated, are less likely to occur with endogenous models.[1] Endogenous models, on the other hand, solve for the point at which the firm will default under optimal conditions. They tend to provide more insight in terms of the default process (when firms default) and allow for meaningful comparative statics (how default probabilities change with respect to the underlying variables). However, that is not to say structural models with exogenous default are useless; in fact, exogenous default models still make many

contributions to the analysis of credit risk, just in different capacities. It will be shown that imposing exogenous default allows for interesting real-world features to be incorporated into the model, including deviations from the absolute priority rule and mean-reverting leverage ratios.

Structural credit risk models were pioneered by the seminal works of Black and Scholes (1973) and Merton (1974), who noted that the equity is essentially a call option on the firm's assets when the firm has debt in its capital structure. Though the insight was groundbreaking, the model is overly simple to the point where using it to model real-world credit risk becomes rather implausible. Jones et al. (1984) confirmed this empirically where it was shown that the basic Black-Scholes-Merton (BSM) model generates credit spreads that are smaller than are actually observed.[2] As such, in the decades that followed researchers have developed, implemented, and tested extensions to the basic BSM model utilizing the contingent-claims framework but incorporating more realistic features of corporate debt. In fact, the literature on structural credit risk models has become so extensive that a comprehensive survey could be a book in and of itself. Instead, this paper focuses on a handful of popular structural credit risk models: two with endogenous default and three with exogenous default (in

---

[1] Of course, the parameters in a structural credit risk model can still be "tweaked" to obtain desirable results, but the risk of modeler manipulation is present with any financial model.

[2] The result is that the BSM model *overprices* risky debt.

Table 56.1 Select structural credit risk models and their features

Model	Default	Recovery	Interest rates
Black and Cox (1976)	Exogenous Exponential barrier	Fixed fraction of present value of face value of debt	Deterministic
Longstaff and Schwartz (1995)	Exogenous Flat barrier	Allows for violations of ARP	Stochastic
Collin-Dufresne and Goldstein (2001)	Exogenous Mean-reverting barrier (stationary leverage)	Same as Longstaff-Schwartz	Stochastic
Geske (1977) Geske and Johnson (1984)	Endogenous Function of liabilities	Asset value at default	Deterministic
Leland (1994) Leland and Toft (1996)	Endogenous Flat barrier	Fixed proportion of asset value	Deterministic

addition to the BSM and KMV). These models and their main features are outlined in Table 56.1.

The remainder of the chapter is organized as follows. In Section 56.2 two basic structural models are discussed: the original Black-Scholes-Merton model and the Moody's-KMV model as used in the literature.[3] Section 56.3 discusses three structural credit risk models with exogenous default and Section 56.4 discusses two structural credit risk models with endogenous default. Finally, Section 56.5 concludes.

56.2 The Basic Model

56.2.1 Black-Scholes-Merton (BSM)

One of the first papers to discuss pricing debt and other corporate liabilities as contingent claims on the underlying firm value was Black and Scholes (1973). Although this paper is usually cited for its contribution to option pricing theory, the last few sections deal with the more subtle problem of accurate valuation of corporate securities, including common stock and corporate bonds.

The concept of option pricing lends itself quite nicely to the valuation of corporate securities. When a firm's capital structure contains debt, the equity can be seen as a long call option on the firm's asset value. When the debt is in the form of a discount bond paying F at maturity time T, then the equity is worth $Max\{V_T - F, 0\}$ at maturity, where V_T is the terminal value of the firm's assets at maturity time T. This is exactly the same payoff at expiration of a long European call option with strike price F. The equilibrium price of a contingent claim paying $V_T - F$ if $V_T > F$, and nothing otherwise, is found by solving a partial differential equation that describes the functional relationship between the contingent claim and the underlying asset subject to the boundary conditions, $E(V_T, T) = V_T - F$, if $V_T > F$; 0, if $V_T \leq F$. When the asset value evolves according to a Geometric Brownian Motion, then the intertemporal equilibrium value of equity is the value of the contingent claim E_t as defined by the well-known Black-Scholes formula:

$$E_t = V_t N(d_1) - Fe^{-r(T-t)}N(d_2) \qquad (56.1)$$

where, $d_1 = \frac{\ln\left(\frac{V}{F}\right) + \left(r + \frac{1}{2}\sigma^2\right)(T-t)}{\sigma\sqrt{T-t}}$; $d_2 = \frac{\ln\left(\frac{V}{F}\right) + \left(r + \frac{1}{2}\sigma^2\right)(T-t)}{\sigma\sqrt{T-t}}$.

The function $N(\cdot)$ is the cumulative normal distribution function.

Since the sum of the market value of debt and the market value of equity must equal the market value of the assets, then by definition the intertemporal equilibrium value of the debt is $V_t - E_t$. This implies that the bondholders essentially own the firm's assets and sell a call option on the assets to the stockholders. Since, in this basic setup, the debt is a pure discount bond, the bondholders pay less than the face value F at time 0, where the discount is $F - (V_0 - E_0)$. At maturity, time T, the bondholders either get the face value of the debt (F) or, if the value of the assets is not high enough to cover the face value, then the firm is "bankrupt" and the bondholders own the assets at value V_T (i.e. the call option is not exercised). The difference between the amount paid at time 0 and F consists of both the time value and the premium due to default risk.

There is another way to look at the debt of a firm, arising from the put-call parity identity first explicated by Stoll (1969). Put-call parity links four different markets: the call option market, the put option market, the market for the underlying asset, and the [risk-free] money market. It states that the value of a portfolio consisting of a long call option (with strike price X and maturity T) and cash equal to the present value of the strike price must be equal to a portfolio consisting of a long position in the underlying asset and a long put option (also with strike price X and maturity T). In symbols, this says $c_t + PV(X) = S_t + p_t$. When E_t is a long call option on the firm value (V_T) with strike price equal to the face value of debt (F), we get $E_t + PV(F) = V_t + p_t$. Rearranging, we see that the value of the risky discount bond described above is $V_t - E_t = PV(F) - p_t$. This decomposes the risky bond into two parts: the present value of the principal that is lent ($PV(F)$) and a short put option on the firm's assets ($-p_t$). The former is the pure time value at the risk-free rate; the latter is the default risk premium.

When a firm's capital structure consists of just equity and one class of non-coupon paying debt, the rearranged put-call parity identity can be thought of as a capital markets equilibrium condition that links the value of the firm's assets, the value of the common stock, and the value of risky debt (which consists of pure time value and value attributed to the risk of default).

Merton (1974) adds to the Black and Scholes (1973) analysis with an entire paper dedicated to the idea of applying option pricing methodology to value risky debt. The paper seeks to quantify the increase or decrease in the prices of bonds that result from changes in the probability that an issuer will not be able to satisfy their debt obligations (i.e. default risk). As the paper focuses on the "risk structure of interest rates", Merton attempts to isolate the impact of default risk by assuming a flat term structure with a constant risk free rate. However, this assumption is not only unrealistic but is also quite problematic and may explain why the basic BSM structural model tends to overprice debt in reality.

The Merton (1974) paper is much more mathematically rigorous than the Black and Scholes (1973) paper and contains complete comparative statics of the debt value as a function of the underlying firm value, the degree of leverage ("'quasi' debt-to-firm value ratio"), the volatility of the firm, and the time-to-maturity. The same comparative statics are reproduced using the default risk premium (defined as the difference between the yield-to-maturity on the risky bond and the risk-free rate).

Aside from the flat yield curve assumption, there are several other simplifications in the Merton (1974) model that make it impractical and unrealistic. These simplifications and the problems resulting from them provide much of the impetus for the extensions that would emerge over the following years. The basic Merton (1974) model assumes that the firm only has one issue of debt outstanding and that the issue consists of non-coupon paying debt. This is probably unrealistic as many firms have several different debt issuances in their capital structure at a given time and quite often they are of different priority and maturity. Most bonds also pay coupons, either fixed or floating rate.[4] Next section, a practical implementation of the BSM structural credit risk model – the Moody's-KMV model – is discussed. The Moody's-KMV model is also a single-period model, but it incorporates more information about the liability structure (short-term and long-term debt) and is often used to construct an ad-hoc term structure of default probabilities.

56.2.2 Moody's-KMV (MKMV)

The Moody's-KMV (MKMV) structural credit risk model is a practical implementation of the original BSM model with certain modifications to reflect empirically observed characteristics of default. The model was developed by KMV corporation which was subsequently acquired by Moody's Corporate in 2002. The true KMV model used for commercial purposes is proprietary and can be considered a "black box"; however, a well-known version described in the technical document by Crosbie and Bohn (2003) is commonly used in industry and in academic studies.[5]

The MKMV model has exogenous default, but unlike the BSM model, the default barrier is not assumed to be the face value of all debt. Rather Crosbie and Bohn (2003) note that, empirically, default typically occurs at values *below* the total face value of debt. Since short-term debt represents a more immediate constraint, that is usually taken at 100 % of face value for the barrier; to this, a fraction of the outstanding long-term debt is then added. Letting K_{MKMV} denote the default barrier for the Moody's-KMV model, it is generally accepted in the literature to specify it as:

$$K_{KMV} = ST + \frac{1}{2}LT \qquad (56.2)$$

where ST denotes the total face value of short-term liabilities and LT denotes the total face value of long-term liabilities. This default barrier is then used as the strike price in the Black-Scholes formula for computing the European call option value. The other inputs are: the market value of the firm's assets (V), the asset volatility (σ_V), the risk-free rate (r), and the default horizon (T). Now, however, the modeler is faced with an "inverse problem"—specifically, two of the inputs are unobservable (asset value and asset volatility) whereas the output (equity value) *is* observable. There is a clever solution to this problem. From Ito's Lemma we can specify the relationship between equity volatility (observable) and asset volatility (unobservable), in closed-form. In general, this relationship is[6]:

$$\sigma_E E = \sigma_V V \frac{\partial E}{\partial V}. \qquad (56.3)$$

---

[4] It should be noted that at the end of the paper Merton (1974) does in fact address the pricing of coupon paying bonds; however, the valuation is significantly more complicated and very impractical to apply in practice.

[5] In fact, quite often this version of the KMV structural model is used as a benchmark default model against which others are compared in the academic literature. See, for instance, Bharath and Shumway (2008), Leland (2004), etc.

[6] This is true not only for Black-Scholes options but for any contingent claims.

In the Black-Scholes model, it is well known that the partial derivative of the call option value with respect to the underlying asset value is known to be $N(d_1)$ from Equation 56.1, the option "Delta", this can be plugged into Equation 56.3 which results in two equations in two unknowns:

$$E = BS_{Call}(V, \sigma_V, K_{MKMV}, T, r)$$
$$\sigma_E = \frac{V}{E}N(d_1)\sigma_V \qquad (56.4)$$

where $BS_{Call}(V, \sigma_V, K_{MKMV}, T, r)$ is the function given in Equation 56.1. In order to solve the system of equations given in Equation 56.4 an iterative numerical procedure has to be used. Typically one selects initial values for V and σ_V, say the book value of assets and some fraction of the empirical equity volatility. Then the algorithm will go back and forth between the two equations seeking to minimize the distance between the model outputs for E and σ_E with the observed values for the market value of equity and empirical equity volatility, respectively.

Once an appropriate default horizon has been chosen, say $T = 1$ year, the MKMV model can then be used to compute the probability that the particular firm will default given the current liability structure (i.e. book value of short-term and long-term debts), the market value of the firm's equity, an estimate of the equity volatility, and the risk-free interest rate. This is the probability that a European call option on the firm's assets expires out-of-the-money where the strike price is equal to the MKMV default barrier (from Equation 56.2) and the option expiration is equal to the default horizon. The default probability is:

$$\Pr\{V_T \leq K_{MKMV}\} = 1 - N(d_2) = N(-d_2) \qquad (56.5)$$

where $N(d_2)$ is defined in the valuation expression in Equation 56.1.

Another metric from the MKMV model that has become popular is the "Distance-to-Default" or DD. The Distance-to-Default shows, for a given horizon T, how many standard deviations away from the default barrier the expected asset value will be T years out. Since it is assumed that asset value follows a Geometric Brownian Motion, the Distance-to-Default is:

$$DD_T = \frac{\ln\left(\frac{V_0}{K_{MKMV}}\right) + \left(\mu - \frac{\sigma^2}{2}\right)T}{\sigma\sqrt{T}}. \qquad (56.6)$$

This happens to be d_2 from Equation 56.1. Consequently, we can rewrite the default probability in Equation 56.5 as $N(-DD_T)$.

Both the original BSM structural credit risk model and the MKMV structural credit risk model have exogenous default, since the default point is defined exclusively in terms of the face values of debts. In the next section, three extensions to this basic structural framework are discussed. All three also have exogenous default, but default can occur at any time in the form of a Markov hitting time.

56.3 Exogenous Default Models

56.3.1 Black and Cox (BC)

Black and Cox (1976) extend the basic structural model to incorporate some specific restrictions that may appear in the bond indenture. These restrictions can affect the conditions under which a firm defaults and, therefore, will have an impact on the pricing of risky debt. They begin with assumptions similar to those made in Merton (1974) leading to the general partial differential valuation equation. The authors point out that the partial differential equation already implies certain restrictions on investment policy, financing policy, and payouts. In this paper, Black and Cox (1976) examine "safety covenants"—contractual provisions that stipulate the firm-specific conditions that force restructuring. There may or may not be an upper boundary on firm value, above which the firm is to call debt. More importantly there is a lower boundary on firm value, below which the firm is "bankrupt"; here the debt holders take control of the firm's assets. Black and Cox (1976) were the first to consider this notion of a default barrier; they note that it may be either exogenous, a given value specified outside the model, or endogenous, where it is actually solved for in the model. Endogenous barriers represent an optimal decision problem, whereas exogenous barriers are specified in the contract. Since the Black and Cox (1976) model deals with safety covenants, the barriers are exogenous. They note that the barrier may take on different forms depending on the specific type of covenant that is being modeled. Perhaps the most well-recognized form is the exponential barrier where bankruptcy is triggered when the asset value V_t falls to the level $K(t) = Ce^{-\gamma(T-t)}$, where C is a constant that may be a function of the initial face value of the debt issued, T is the maturity, and γ is the barrier growth rate.

Assuming that the asset value evolves according to a Geometric Brownian Motion, then this is a Gaussian first passage problem. The default probability, or the probability that the asset value hits the barrier by time τ is

$$1 - N\left(\frac{\ln\left(\frac{V}{Ce^{-\gamma(T-\tau)}}\right) + \left(r - \frac{\sigma^2}{2}\right)\tau}{\sigma\sqrt{\tau}}\right) + \left(\frac{V}{Ce^{-\gamma(T-\tau)}}\right)^{1-2\left(\frac{r-\gamma}{\sigma^2}\right)}$$

$$N\left(\frac{\ln\left(\frac{Ce^{-\gamma(T-t)}}{V}\right) + \left(r - \frac{\sigma^2}{2}\right)\tau}{\sigma\sqrt{\tau}}\right)$$

$$(56.7)$$

where $N(^O)$ represents the cumulative standard normal distribution function.

While arbitrary values can be chosen for C and γ – thereby rendering the default barrier arbitrary – Black and Cox (1976) note that a reasonable and "interesting" choice is to set C equal to ρF and γ equal to the risk-free rate, where $0 \le \rho \le 1$. This implies that the firm will default when asset value equals a specified fraction of the present value of the principal amount borrowed (i.e. the face value). As a result, this imposes an exogenous recovery assumption with a fixed recovery rate of ρ. In this case, $K(t) = \rho F e^{-r(T-t)}$.

The market value of the debt, D_t, can be found as the discounted expected value of the payoffs, which are given by the boundary conditions at maturity and default, respectively:

$$D_T = \min\{V_T, F\} \qquad (56.8)$$

$$D_\tau = \rho F e^{-r(T-\tau)} \qquad (56.9)$$

The value at default, given by Equation 56.9, assumes the recovery rate discussed above. This leads to the following valuation formula for debt:

$$D(t) = F e^{-r(T-t)}\left[N(z_1) - y^{2\theta-2}N(z_2)\right]$$
$$+ V e^{-a(T-t)}\left[N(z_3) + y^{2\theta}N(z_4) + y^{\theta+\zeta}e^{a(T-t)}N(z_5)\right.$$

$$\left. + y^{\theta-\zeta}e^{a(T-t)}N(z_6) - y^{\theta-\eta}N(z_7) - y^{\theta-\eta}N(z_8)\right] \quad (56.10)$$

where

$$y = \frac{Ce^{-\gamma(T-t)}}{V_t}$$

$$\theta = \frac{\left(r - a - \gamma + \frac{\sigma^2}{2}\right)}{\sigma^2}$$

$$\delta = \left(r - a - \gamma - \frac{\sigma^2}{2}\right) + 2\sigma^2(r - \gamma)$$

$$\zeta = \frac{\sqrt{\delta}}{\sigma^2}$$

$$\eta = \frac{\sqrt{\delta - 2\sigma^2 a}}{\sigma^2}$$

$$z_1 = \frac{\ln\left(\frac{V_t}{F}\right) + \left(r - a - \frac{\sigma^2}{2}\right)(T - t)}{\sqrt{\sigma^2(T - t)}}$$

$$z_2 = \frac{\ln\left(\frac{V_t}{F}\right) + 2\ln y\left(r - a - \frac{\sigma^2}{2}\right)(T - t)}{\sqrt{\sigma^2(T - t)}}$$

$$z_3 = \frac{\ln\left(\frac{F}{V_t}\right) - \left(r - a + \frac{\sigma^2}{2}\right)(T - t)}{\sqrt{\sigma^2(T - t)}}$$

$$z_4 = \frac{\ln\left(\frac{V_t}{F}\right) + 2\ln y\left(r - a + \frac{\sigma^2}{2}\right)(T - t)}{\sqrt{\sigma^2(T - t)}}$$

$$z_5 = \frac{\ln y + \zeta\sigma^2(T - t)}{\sqrt{\sigma^2(T - t)}}$$

$$z_6 = \frac{\ln y - \zeta\sigma^2(T - t)}{\sqrt{\sigma^2(T - t)}}$$

$$z_7 = \frac{\ln y + \eta\sigma^2(T - t)}{\sqrt{\sigma^2(T - t)}}$$

$$z_8 = \frac{\ln y - \eta\sigma^2(T - t)}{\sqrt{\sigma^2(T - t)}}$$

and a, which was not previously defined, is the continuous dividend rate; if no dividends are paid – as was assumed earlier – then $a = 0$ and Equation 56.10 simplifies significantly.

The Black and Cox (1976) model offers several advantages. First, it allows default to occur at anytime between now and maturity. However, the fact that default usually occurs at discrete points in time (i.e. when payments are due to creditors) can be viewed as a drawback, which is addressed by other models (see, e.g., the Geske compound option model in Section 4.1). Another advantage is that the model has a closed-form solution and is easy to implement and, in fact, serves as the template for many of the models that are used in industry. The largest disadvantage is that it does not work when bankruptcy is endogenous.

56.3.2 Longstaff and Schwartz (LS)

Longstaff and Schwartz (1995) essentially extend the Black and Cox (1976) model. It incorporates stochastic interest rates by including the Vasicek (1977) mean-reverting term structure dynamics so that the model is a two-factor Markov process. There is a constant, or flat, exogenous default barrier set equal to K. The fact that K is fixed for the life of the firm implies a stationary capital structure. This is achieved by assuming that coupons and principal payments are funded by issuing new debt. There is also an exogenous recovery assumption where, upon default, creditors receive a fixed percentage of face value. This actually allows for violations of the Absolute Priority Rule (APR) which is a nice feature of the model. Longstaff and Schwartz (1995) derive elegant, closed-form solutions for pricing both fixed and floating rate debt with various maturities using the structural credit risk model.

The LS model begins, as most structural credit risk models do, with the assumption that the asset value, V_t, follows a Geometric Brownian Motion. Given the flat barrier, default is modeled as a first passage event. As long as $V_t > K$, then the firm remains solvent; however, once $V_t \leq K$ financial distress is triggered. When the firm is distressed there is assumed to be some reorganization that occurs, which results in debt holders receiving a fraction, $w \leq 1$, of the face value. Since w is the "write-down" on the debt, the recovery rate would be $R = 1 - w$ The authors note that, when a firm has various classes of debt outstanding, there may be different values of w representing differential recovery rates (for instance $w_{sr.}$ and w_{Sub}, for Senior and Subordinated debt, respectively).

The value of a fixed-rate risky discount bond, subject to both interest rate and default risk, is a function of the following variables: $X = \frac{V}{K}$, r, and T, which represent a measure of distance from the default barrier, the [stochastic] interest rate, and the time-to-maturity, respectively; as well as the parameters: α, β, η, ρ, σ, and w, where the first three are interest rate parameters from the Vasicek (1977) model, ρ is the correlation between the Brownian Motion that drives the interest rate dynamics and the Brownian Motion that drives the asset value dynamics, σ is the asset volatility, and w is the "write-down" as described in the last paragraph. Define the face value of the bond with maturity T to be $F(r,T)$ and let $D(X,r,T)$ be the price of a risky discount bond:

$$D(X,r,T) = F(r,T) - wF(r,T)Q(X,r,T) \quad (56.11)$$

where $Q(X,r,T)$ is the risk-neutral default probability defined as the limit where $n \to \infty$ of

$$Q(X,r,T,n) = \sum_{i=1}^{n} q_i$$

$$q_1 = N(a_1)$$

$$q_i = N(a_i) - \sum_{j=1}^{j-1} q_j N(b_{ij}), \quad i = 2,3,...,n$$

$$a_i = \frac{-\ln X - M\left(\frac{iT}{n,T}\right)}{\sqrt{S\left(\frac{iT}{n}\right)}}$$

$$b_{ij} = \frac{M\left(\frac{jT}{n,T}\right) - M\left(\frac{iT}{n,T}\right)}{\sqrt{S\left(\frac{iT}{n}\right) - S\left(\frac{jT}{n}\right)}}$$

where $N(\cdot)$ is the cumulative standard normal distribution function and

$$M(t,T) = \left(\frac{\alpha - \rho\sigma\eta}{\beta} - \frac{\eta^2}{\beta^2} - \frac{\sigma^2}{2}\right)t + \left(\frac{\rho\sigma\eta}{\beta^2} + \frac{\eta^2}{2\beta^3}\right)e^{-\beta T}(e^{\beta t} - 1)$$

$$+ \left(\frac{r}{\beta} - \frac{\alpha}{\beta^2} + \frac{\eta^2}{\beta^3}\right)(1 - e^{-\beta t}) - \left(\frac{\eta^2}{2\beta^3}\right)e^{-\beta T}(1 - e^{-\beta t}),$$

$$S(t) = \left(\frac{\rho\sigma\eta}{\beta} + \frac{\eta^2}{\beta^2} + \sigma^2\right)t - \left(\frac{\rho\sigma\eta}{\beta^2} + \frac{2\eta^2}{\beta^3}\right)(1 - e^{-\beta t})$$

$$+ \left(\frac{\eta^2}{2\beta^3}\right)(1 - e^{-2\beta t}).$$

The LS model can be used to price coupon-paying bonds as a portfolio of these risky discount bonds.

Floating-rate payments are valued as explicit functions of the stochastic interest rate

$$C(X,r,\tau,T) = D(X,r,T)R(r,\tau,T) - wF(r,T)G \\ \times (D,r,\tau,T) \quad (56.12)$$

where

$$R(r,\tau,T) = re^{-\beta\tau} + \left(\frac{\alpha}{\beta} - \frac{\eta^2}{\beta^2}\right)(1 - e^{-\beta\tau}) + \left(\frac{\eta^2}{2\beta^2}\right)e^{-\beta T}$$

$$(e^{\beta\tau} - e^{-\beta\tau})G(X,r,\tau,T,n) = \sum_{i=1}^{n} q_i \frac{K\left(\tau,\frac{iT}{n}\right)}{S\left(\frac{iT}{n}\right)}M\left(\frac{iT}{n},T\right)$$

$$K(\tau,t) = \left(\frac{\rho\sigma\eta}{\beta} + \frac{\eta^2}{\beta^2}\right)e^{-\beta\tau}\left(e^{\beta\min\{\tau,t\}} - 1\right) - \left(\frac{\eta^2}{2\beta^2}\right)e^{-\beta\tau}e^{-\beta\tau}$$

$$\left(e^{2\beta\min\{\tau,t\}} - 1\right)$$

and $G(X,r,\tau,T)$ is the limit of $G(X,r,\tau,T,n)$ as $n \to \infty$. Floating-rate coupon bonds can be valued as the sum of floating rate cash flows in Equation 56.12 plus the value of the principal from Equation 56.11.

Longstaff and Schwartz (1995) are able to perform some interesting empirical analysis using their model. Many of the insights stem from correlations between credit spreads, interest rates, and equity returns. For instance, when regressing changes in credit spreads (from Moody's bond yield data) on changes on Treasury yields and returns on an appropriate equity index, they find that the coefficient on both interest rates and equity returns are negative, although significance varies across industries and credit ratings. This is consistent with the LS model, which implies that credit spreads tighten as interest rates increase and credit spreads are negatively related to equity returns. The latter point is very intuitive from a credit risk perspective: holding all else constant, an increase in equity corresponds to an increase in asset value which results in lower leverage and lower default probabilities. Lower default probabilities should be reflected in a smaller default risk premium and tighter credit spreads. The key innovation, and indeed one of the main contributions, lies in the impact of stochastic interest rates on credit spreads and bond prices.

56.3.3 Collin-Dufresne and Goldstein (CDG)

Collin-Dufresne and Goldstein (2001) claim that target leverage ratios affect credit spreads. They develop a structural model of debt that allows for mean-reverting leverage and show that this model produces credit spreads that are more in line with those observed empirically. The Collin-Dufresne and Goldstein (2001)—referred to as CDG—model is a direct extension of the Longstaff and Schwartz (1995) model that includes a stochastic default boundary and an option to add more debt. This option adds value and seems to be reflected in credit spreads.

Most structural models assume a static capital structure of the firm; that is to say that the firm cannot and does not act to dynamically add or reduce debt.,[7, 8] However, this behavior is not representative of how firms act. Collin-Dufresne and Goldstein (2001) argue that the valuation of debt must take into account not only the firm's current leverage but also the option to increase this leverage in the future; ignoring this option can result in the mispricing of debt within the structural model. Specifically, the authors claim that the firm's option to issue more debt should increase credit spreads on current outstanding debt. The intuition for why is rather

straightforward: a firm not constrained with respect to future capital structure is likely to take on more debt in the future if conditions are favorable. This possibility makes default more likely in the future than if capital structure was restricted and, therefore, debt holders are going to price the current outstanding debt to account for this added risk. There is empirical evidence that leverage ratios are stationary, which implies that as firm value rises (falls), the firm will issue (repurchase) debt. Thus, a structural credit risk model should be able to account for these changes in the default barrier, moving up and down with leverage. However, we do not know when these changes will occur and so leverage, and consequently the barrier, is modeled as a stochastic process itself. The CDG model is therefore an exogenous barrier model, like the other models discussed thus far. The difference is that the barrier is not flat or following some deterministic function, but itself is driven by randomness. The mechanisms for this process will be discussed next.

Assuming that the asset value dynamics follow a Geometric Brownian Motion, then asset values, V_t, are lognormally distributed. In the Collin-Dufresne and Goldstein (2001) paper everything is converted to log-values for convenience. Therefore, the main state variable is going to be $y_t = \log V_t$. Next define the "log-default threshold", k_t, which represents a log-transformation of debt at time t. Then, the log-leverage is $l_t = k_t - y_t$. The log-leverage follows a mean-reverting Markov process, where the stochastic component comes from the Wiener process driving y_t; the mean-reversion comes from the fact that k_t adjusts based on its proximity to y_t (when k_t is high the barrier decreases and when k_t is low the barrier increases). Note that there are two Brownian Motions in the model: one for the asset value and another for the interest rate. Since the mean-reverting leverage process is actually driven by the same random factor as the asset value process, the CDG model can be thought of as a "two-and-a-half factor" structural credit risk model. The target leverage ratio is actually a decreasing function of the current interest rate, which reflects that firms increase leverage when interest rates are low and decrease leverage when interest rates are high. The model yields several other results that appear to be consistent with empirical evidence about credit markets. Whereas previous structural credit risk models have performed poorly in generating credit spreads and for bond pricing (see, e.g., Jones et al. (1984) and Eomet al. (2004)), the CDG model provides a theoretical basis for explaining these discrepancies. In fact, recent work by Flannery et al. (2011) empirically confirm that changes in credit spreads reflect not only the current leverage ratio but also the market's expectations about *future* leverage ratios. This represents a major breakthrough towards understanding the impact of capital structure decisions on the dynamics of bond prices, credit spreads, and default probabilities. However, as will be discussed in the

---

[7] The Geske (1977) compound option structural credit risk model new equity is raised to pay down outstanding debt. This is not a dynamic rebalancing of the capital structure, but rather a systematic reduction in the amount of leverage in a manner that is typically not seen in practice. This will be discussed in detail in Section 56.4.1.

[8] Goldstein et al. (2001) do in fact develop a structural model for dynamic capital structure.

next section, the incorporation of endogenous default into a structural credit risk model provides a more integrative way to unify capital structure decisions and the various dimensions of credit risk.

56.4 Endogenous Default Models

56.4.1 Geske (G)

Geske ([1977](#)) and Geske and Johnson ([1984](#)) value corporate securities (both debt and equity) as *compound options*. The compound option approach has endogenous default and, while distinct from the typical barrier/first-passage structural models, can be thought of as a discrete barrier. This approach was originally proposed by Geske ([1977](#)), who noted that when there are multiple cash flows, in the form of coupon payments and/or several classes of debt outstanding, then equity is a *compound* call option on the firm's assets.[9] A compound call option is a call option on a call option. Each cash flow is therefore a strike price for the compound option. Whenever a payment is due to bondholders, the firm's shareholders must decide whether or not to exercise the compound call option. Making the payment represents exercising the compound call option, thereby agreeing to continue holding a sequence of contingent claims on the firm's assets. When there are two cash flows the model solution is known in closed-form using the compound option formulae from Geske ([1979](#)). This set-up is useful for valuing risky debt when the liability structure is bifurcated into short-term and long-term debt or junior and senior debt. Geske and Johnson ([1984](#)) appropriately specify the default conditions when there are two distinct classes of debt, which leads to the correct closed-form expression for the intertemporal values of equity, junior, and senior debt.

Let the value of the firm's assets follows a Geometric Brownian Motion satisfying the stochastic differential equation

$$dV_t = r_t V_t dt + \sigma_V V_t dW_t \qquad (56.13)$$

where dW_t represents a standard Brownian increment under the risk-neutral probability measure. Then the valuation of the corporate securities in this framework are given by the expectation of the discounted future payoffs under the risk-neutral measure. For equity that is

---

[9] The idea of modeling coupon-paying debt as a compound option was actually proposed by Black and Scholes ([1973](#)) [see pp. 651–652]; however, compound options cannot be priced by the standard Black-Scholes valuation formula.

$$\mathbb{E}\left[e^{-rT_1}\max\{E_{T_1} - F_1, 0\}\right] \qquad (56.14)$$

where F_1 is the face value of the senior debt with maturity time T_1. E_{T_1} is actually the Black-Scholes value of the European call option expiring at time $T_2 > T_1$ (T_2 is the maturity time for the junior debt which has face value F_2). The value E_{T_1} is not known at the current time $t = 0$, and plays a key role in determining the endogenous default point in the compound option structural model. The expectation given in Equation [56.14](#) is equal to

$$E_{t=0} = V_{t=0} N_2\left(h_1^+, h_2^+; \rho\right) - F_2 e^{rT_2} N_2\left(h_1^-, h_2^-; \rho\right)$$
$$\qquad - F_1 e^{-rT_1} N\left(h_1^-\right) \qquad (56.15)$$

where $h_1^+ = \dfrac{\ln\left(\frac{V_t}{\bar{V}}\right) + \left(r + \frac{\sigma^2}{2}\right)\tau_1}{\sigma\sqrt{\tau_1}}$,

$$h_1^- = \frac{\ln\left(\frac{V_t}{\bar{V}}\right) + \left(r - \frac{\sigma^2}{2}\right)\tau_1}{\sigma\sqrt{\tau_1}} = h_1^+ - \sigma\sqrt{\tau_1},$$

$$h_2^+ = \frac{\ln\left(\frac{V_t}{F_2}\right) + \left(r + \frac{\sigma^2}{2}\right)\tau_2}{\sigma\sqrt{\tau_2}},$$

$$h_2^- = \frac{\ln\left(\frac{V_t}{F_2}\right) + \left(r - \frac{\sigma^2}{2}\right)\tau_2}{\sigma\sqrt{\tau_2}} = h_2^+ - \sigma\sqrt{\tau_2},$$

$N(\cdot)$ denotes the cumulative standard normal distribution, $N_2(\cdot)$ denotes the cumulative bivariate standard normal distribution, and correlation $\rho = \sqrt{\frac{\tau_1}{\tau_2}}$ which follows from the properties of Brownian Motion.
$\bar{V}$ is the endogenous default boundary.

Now, the senior debt has face value F_1 and is to be paid at time T_1. Holders of the senior debt will receive either the total amount they are promised (i.e. no default) or, in the event there is a default, the assets will be liquidate and they will receive the market value of the assets at time T_1. Thus, the value of the senior debt at time $t = 0$ is given by the expectation

$$\mathbb{E}\left[e^{-rT_1}\min\{V_{T_1}, F_1\}\right]. \qquad (56.16)$$

It is fairly straightforward to show that the expectation given in Equation [56.16](#) is equal to

$$S_0 = V_0[1 - N(k^+)] + F_1 e^{-rT_1} N(k^-) \qquad (56.17)$$

where $k^+ = \dfrac{\ln\left(\frac{V_t}{F_1}\right) + \left(r + \frac{\sigma^2}{2}\right)\tau_1}{\sigma\sqrt{\tau_1}}$ and $k^- = \dfrac{\ln\left(\frac{V_t}{F_1}\right) + \left(r - \frac{\sigma^2}{2}\right)\tau_1}{\sigma\sqrt{\tau_1}}$ $= k^+ - \sigma\sqrt{\tau_1}$.

Then, finally, the value of the junior debt at time $t = 0$ is given by the expectation:

$$\mathbb{E}\left[e^{-rT_1}\left(\left(J_{T_1} \cdot \mathbb{I}_{\{V_{T_1} > \bar{V}\}}\right) + \left(\max\{V_{T_1} - F_1, 0\} \cdot \mathbb{I}_{\{V_{T_1} \leq \bar{V}\}}\right)\right)\right]$$
(56.18)

where $\mathbb{I}_{\{V > \bar{V}\}}$ is the indicator function that equals 1 if $V > \bar{V}$ and 0 otherwise.

To obtain the closed-form solution for the junior debt, the expectation given in Equation 56.18 can be evaluated directly or, since the expectation for the senior debt is considerably more straightforward, the fact that $V_t = E_t + J_t + S_t$ can be used to solve for $J_t = V_t - E_t - S_t$, at any time t. Subtracting Equations 56.15 and 56.17 from V_0 gives:

$$\begin{aligned} J_0 = &V_0\left[N(k^+) - N_2\left(h_1^+, h_2^+; \rho\right)\right] \\ &+ F_1 e^{-rT_1}\left[N\left(h_1^-\right) - N(k^-)\right] \\ &+ F_2 e^{-rT_2} N_2\left(h_1^-, h_2^-; \rho\right) \end{aligned}$$
(56.19)

where everything defined in Equations 56.15 and 56.17 remain the same.

When there are more than two cash flows, the compound option model is known in "quasi-closed-form" in that it can be written out, but not solved analytically. Therefore, numerical methods must be used in these instances to both value the corporate securities as well as compute default probabilities. Default is endogenously determined at every cash flow, and as a result the model is able to generate a complete term structure of default probabilities. This concept of a complete term structure of default probabilities will be elaborated on shortly.

In the compound option framework, the endogenous default condition is as follows. Every time a payment is due, a decision has to be made as to whether or not the firm should default. If the asset value is sufficiently high, then there is a non-zero equity value; under the assumption of perfect markets, new equity can be raised at the current price and the proceeds used to make the imminent payment to creditors. When asset value drops, so does the value of the equity, which is a contingent claim on the assets. If the asset value gets too low, then adequate equity cannot be raised to satisfy the next obligation and the shareholders choose to *not exercise* the compound call option (i.e. default) and creditors take control of the assets in accordance to absolute priority. Thus, default is endogenously determined as the asset value that sets the value of equity just equal to the next cash flow. If the asset value falls below this level it implies negative equity value. This condition (inability to raise capital to service debt and/or negative equity value) is similar to other models with endogenous default.

Stated more formally, at every cash flow time there exists a critical asset value, $V_{T_i} = \bar{V}$, that solves the integral equation:

$$E_{T_i}(\bar{V}) - F_i = 0.$$
(56.20)

In fact, the solution to this integral equation implies that the critical asset value is exactly equal to the face value of the next cash flow plus the present value of the expected remaining cash flows thereafter. Therefore, the discrete default barrier – constructed as the sequence of critical asset values at each cash flow – reflects the firm's ability to raise capital to satisfy the next obligation as well as the asset value capacity to cover the expectation of remaining payments.

The compound option structural model assumes that new equity is issued to pay down maturing debts. This implies that, in the Geske framework, the firm in question is expected to systematically reduce its leverage over time. This assumption may be unrealistic in modeling many firms and, indeed, a major criticism of the compound option structural model is that it imposes this financing restriction. As we will see, other structural models treat the financing of maturing debt differently, which directly impacts the shape and form of the default barrier over time.

In the compound option structural credit risk model there is a default probability associated with each and every cash flow over time. As a result the compound option model explicitly gives a complete term-structure of default probabilities. The term structure of default probabilities is not just a curve of the cumulative default probabilities, which can be computed with any barrier structural credit risk model; rather it includes both conditional and unconditional forward default probabilities (i.e. marginal and joint probabilities). In the two cash flow case all of the default probabilities are known in closed-form and will be presented below.

The first probability to define is the short-term survival probability, or the probability that at time T_1 the asset value is greater than the endogenous default point. Under the risk-neutral measure this is:

$$\Pr\{V_{T_1} > \bar{V}\} = N\left(h_1^-\right)$$
(56.21)

where $N\left(h_1^-\right)$ is as defined in the valuation equations above (see, e.g., Equation 56.15).

The short-term default probability, $DP(T_1)$, can now be easily defined as $1 - N\left(h_1^-\right)$ or $N\left(-h_1^-\right)$. Since the two events – surviving past the first cash flow and defaulting at time T_1 – are mutually exclusive, the probability that the asset value at time T_1 is less than or equal to the endogenous default boundary is equal to one minus the probability given in Equation 56.21.

$$\Pr\{V_{T_1} \leq \bar{V}\} = 1 - \Pr\{V_{T_1} > \bar{V}\} = 1 - N(h_1^-)$$
$$= N(-h_1^-). \tag{56.22}$$

The next probability to define is the total survival probability, which is the joint probability of surviving to both T_1 and T_2. This can be done by making use of the properties of Brownian Motion and the fact that the two events – the asset value at T_1 being greater than the endogenous default boundary and the asset value at T_2 being greater than the face value of the junior debt – are jointly lognormal. It can be shown that under the risk-neutral measure this is equal to $N_2(h_1^-, h_2^-; \rho)$ defined in the valuation equations above (see, Equation 56.15). Thus, the total survival probability is:

$$\Pr\{(\ln V_{T_1} > \ln \bar{V}) \; \& \; (\ln V_{T_2} > \ln F_2)\}$$
$$= N_2(h_1^-, h_2^-; \rho). \tag{56.23}$$

The forward default probability is easy to compute once the short-term survival probability and the total survival probability are known. The forward default probability is defined as the probability that the long-term debt obligations will not be satisfied given that the short-term debt obligations have been satisfied, or $\Pr\{V_{T_2} > F_2 | V_{T_1} > \bar{V}\}$. This is equal to one minus the conditional survival probability, or $1 - \Pr\{V_{T_2} > F_2 | V_{T_1} > \bar{V}\}$. The conditional survival probability is obtained by applying Bayes' Theorem to the short-term and total survival probabilities, which have already been proved to be $N(h_1^-)$ and $N_2(h_1^-, h_2^-; \rho)$, respectively. It can be shown that the conditional survival probability is $\frac{N_2(h_1^-, h_2^-; \rho)}{N(h_1^-)}$. Therefore the forward default probability is:

$$\Pr\{V_{T_2} \leq F_2 | V_{T_1} > \bar{V}\} = 1 - \frac{N_2(h_1^-, h_2^-; \rho)}{N(h_1^-)} \tag{56.24}$$

When there are n cash flows, there is a complete n-dimensional term structure of default probabilities (as well as survival probabilities) and $(n\text{-}1)$-dimensional forward default probabilities. However, since the solutions are not known in closed-form everything must be computed using numerical methods (see, e.g., Chen et al. 2012).

56.4.2 Leland/Leland and Toft (LT)

Leland (1994) developed a structural credit risk model with endogenous default and, by including taxes and bankruptcy costs, was able to provide an analytical link between a firm's credit risk and its optimal capital structure. The model is set up as a first-passage problem and begins with many of the same assumptions as Black and Cox (1976). The asset value, V_t, evolves according to a Geometric Brownian Motion.

Debt and equity are contingent claims on asset value, denoted by $D(V_t)$ and $E(V_t)$ respectively, both of which are known in closed form. The model assumes one class of debt with infinite maturity and a fixed coupon. The result is a flat, time-invariant default barrier, which is *endogenously determined* as the lowest possible asset value for which equity is still positive. Leland (1994) includes parameters for the corporate tax rate, τ, and bankruptcy cost, $\alpha \in [0, 1]$. This permits an optimal capital structure; something that previously had not appeared in a structural credit risk model (structural credit risk models typically assume that the capital structure decisions are exogenous to the model). To recap, in the Leland (1994) model the solutions for the values of debt and equity as well as the endogenous default barrier and the optimal capital structure are all known and given in closed-form.

Leland and Toft (1996) extend the Leland (1994) model to take debt maturity into account. All of the features from the original Leland (1994) model are preserved – including endogenous default, optimal capital structure, risky debt valuation, and complete closed-form solutions – with additional insights about the term structure of credit spreads and default probabilities. The Leland and Toft (1996) model assumes that every instant a fraction of the outstanding debt is retired at par and refinanced by issuing new debt with the same features (maturity, coupon, etc.) at the current market value. Essentially the firm is being modeled to systematically roll-over debt, which gives rise to a flat default barrier and a stationary debt structure.

The endogenous default barrier is derived using the "smooth-pasting condition". The mathematics translates perfectly into economic intuition in justifying the default conditions. Since the shareholders look to maximize equity value, they will choose an optimal default boundary, V_B, that satisfies the following:

$$\left. \frac{\partial E(V; V_B, T)}{\partial V} \right|_{V=V_B} = 0 \tag{56.25}$$

The solution for the endogenous default boundary is:

$$V_B = \frac{\left(\frac{C}{r}\right)\left(\frac{A}{rT} - B\right) - A\left(\frac{P}{rT}\right) - \tau\left(\frac{C}{r}\right)(a+z)}{1 + \alpha(a+z) - (1-\alpha)B} \tag{56.26}$$

where
$a = \frac{\left(r - \delta - \frac{\sigma^2}{2}\right)}{\sigma^2}$ and $z = \frac{\left[(a\sigma^2)^2 + 2r\sigma^2\right]^{1/2}}{\sigma^2}$;

$$A = 2ae^{-rT}N\left(a\sigma\sqrt{T}\right) - 2zN\left(z\sigma\sqrt{T}\right) - \frac{2}{\sigma\sqrt{T}}N'\left(z\sigma\sqrt{T}\right)$$
$$+ \frac{2e^{-rT}}{\sigma\sqrt{T}}N'\left(a\sigma\sqrt{T}\right) + (z-a)$$

$$B = -\left(2z + \frac{2}{z\sigma^2 T}\right)N\left(z\sigma\sqrt{T}\right) - \frac{2}{\sigma\sqrt{T}}N'\left(z\sigma\sqrt{T}\right)$$
$$+ (z - a) + \frac{1}{z\sigma^2 T}$$

$N(\cdot)$ is the cumulative standard normal distribution, i.e.

$N(x) = \int_{-\infty}^{x} \frac{1}{\sqrt{2\pi}} e^{\frac{-(u)^2}{2}} du$, and

$N'(\cdot)$ is the standard normal density function, i.e. $N'(x) = \frac{1}{\sqrt{2\pi}} e^{-(x)^2 2}$.

Note that Equation 56.26 is a function of the following model parameters:

- r : the risk-free interest rate
- σ : the asset volatility
- δ : the continuous payout rate
- α : bankruptcy cost (the asset write-down on default)
- τ : the corporate tax rate
- P : the total debt principal
- C : the total coupon payments to bondholders (per annum)
- T : the time-to-maturity of the debt.

This last point is very important. Whereas structural credit risk models with exogenous default specify the barrier independent of debt maturity, the endogenous default barrier of Leland and Toft (1996) is an explicit function of the debt maturity. This is what allows the authors to derive optimal maturity structure in addition to everything else. There is also a lot of useful insight that can be obtained by examining the comparative statics with respect to the endogenous default boundary. For instance, one can use Ito's Lemma to compute the total differential of equity as a function of asset value at the default boundary. Specifically,

$$dE|_{V=V_B} = \frac{1}{2}\sigma^2 V^2 \frac{\partial^2 E}{\partial V^2}\Big|_{V=V_B} dt. \tag{56.27}$$

This will illustrate precisely what happens to shareholders' wealth as asset value approaches the endogenous bankruptcy trigger. Equation 56.27 simplifies to:

$$dE|_{V=V_B} = \left((1-\tau)C + \frac{P}{T}\right)dt$$
$$- (dD(V_B) + \delta V_B)dt \tag{56.28}$$

$$dE|_{V=V_B} = \left((1-\tau)C + \frac{P}{T} - \frac{(1-\alpha)}{T}V_B - \delta V_B\right)dt. \tag{56.29}$$

The first term in the parentheses in Equation 56.29 is the annual after-tax coupon payment to bondholders; the second term is the annual rate at which debt principal is paid down;

the third term can be shown to be the market value of debt at; and finally the last term is portion of asset value that is paid out over time dt. Letting $D(V)$ denote the market value of debt, then the market value of debt rolled over each year can be written as $\frac{D(V)}{T}$ and Equation 56.29 can be rewritten as

$$dE|_{V=V_B} = \left[(1-\tau)C + \frac{P}{T}\right]dt - \left[\frac{D(V_B)}{T} + \delta V_B\right]dt \tag{56.30}$$

The sum of the terms in the first set of brackets essentially shows the funds paid out annually: the after-tax coupon plus the face value of the debt that is being retired. The sum of the terms in the second set of brackets represents the funds that are coming in: the market value of new debt that is being raised (to replace the old debt that has been paid down) plus the cash-flow generated by the firm's assets. This is all happening in continuous time and therefore instantaneously. The left-hand-side of Equation 56.30 is the incremental change in equity value at default as a function of asset value. So, at any given time, the firm is paying out the [instantaneous] after-tax coupon plus the portion of debt that is being retired; simultaneously, funds are coming into the firm from both the issuance of new debt and the cash-flow generated by the firm's assets. If the instantaneous debt obligations (principal amount plus coupon payments) cannot be covered by the funds coming in, then shareholders must contribute the cash needed to fill the shortfall. The firm will default when the change in equity value is exactly equal to the additional amount needed to service the debt. Therefore the endogenous default condition implies that firm survival relies on the ability to raise capital. Note that this is very similar to the default condition in the compound option structural credit risk model discussed in the previous section. However, in the compound option structural model, recall that payments to debt holders were entirely financed by issuing new equity and the firm will default when the value of equity just equals the next cash flow. This condition ensures that, when the firm is solvent, new equity can be raised to pay down the maturing debts. This is in contrast to the Leland and Toft (1996) model that essentially requires raising equity only when the new debt raised cannot cover the maturing debt. Once the shareholders no longer find it advantageous to fill this gap, the firm will default. Since the debts are continuously being rolled-over the default boundary is constant resulting in a flat default barrier.

In the LT model, the probability of default can be computed analytically in terms of the first passage density using the endogenous default boundary, V_B, as the barrier. Define the first passage time (or the first hitting time) as

$$t^* = \inf\{t \geq 0 : V_t \geq V_B\} \qquad (56.31)$$

then the default probability, or the probability of hitting V_B at or before time t^*, is

$$F(t^*) = N\left(\frac{-\ln\left(\frac{V}{V_B}\right) - \left(r - \delta - \frac{\sigma^2}{2}\right)t^*}{\sigma\sqrt{t^*}}\right)$$
$$+ \left(\frac{V}{V_B}\right)^{-2\left(\frac{r-\delta-\frac{\sigma^2}{2}}{\sigma^2}\right)}$$
$$N\left(\frac{-\ln\left(\frac{V}{V_B}\right) + \left(r - \delta - \frac{\sigma^2}{2}\right)t^*}{\sigma\sqrt{t^*}}\right). \qquad (56.32)$$

Leland (2004) examines the ability of structural credit risk models to fit historical default frequencies. Using aggregate-level data, he computes default probabilities using two barrier structural models (the endogenous LT model and the exogenous LS model) as well as the KMV Distance-to-Default method. Not surprisingly, all three models result in different default probability curves. The LT model fits the data fairly well for investment grade debt (Baa-rated), but underestimates default rates on speculative grade debt (single B rated). The LS model does not fit actual default frequencies well, except when the parameters are chosen so that it coincides with the endogenous barrier. The KMV model generates default probabilities that level off over longer-term horizons, which is not observed in the empirical data.[10] Furthermore, Leland (2004) shows that, contrary to popular belief, the KMV Distance-to-Default is not a sufficient statistic for probability of default.

56.5 Conclusion

This chapter surveyed the literature on structural credit risk models, specifically making the distinction between models with endogenous default versus those with exogenous default. Models with exogenous default impose an arbitrary default barrier, and therefore default probabilities can be manipulated by modifying the assumptions related the barrier. Endogenous models, on the other hand, do not assume arbitrary default conditions but rather solve for the point at which the firm will default under optimal conditions.

Furthermore, they provide more insight in terms of the default process (when firms default) and allow for meaningful comparative statics (how default probabilities change with respect to the underlying variables). However, it was shown that imposing exogenous default allows for interesting real-world features to be incorporated into the model.

For instance, Longstaff and Schwartz (1995) and Collin-Dufresne and Goldstein (2001) both have structural credit risk models with exogenous default barriers that incorporate stochastic interest rates.[11] Longstaff and Schwartz (1995) explicitly allows for violations of absolute priority; the absolute priority rule, or APR, is quite often an assumption in most structural credit risk models. Their model was one of the first structural credit risk models that enabled the pricing of both fixed rate and floating rate debt. The implementation uses a relative valuation approach across a firm's debt classes and, in that respect, could potentially be applied to studying bond arbitrage.[12] Collin-Dufresne and Goldstein (2001) extended this model to allow for mean-reverting leverage ratios. Mean-reverting leverage ratios have been observed empirically and imply that firms issue and redeem debt to meet target capital structures. By incorporating this into a structural credit risk model they are able to generate credit spreads that are more consistent with those observed in financial markets.

The Geske model has endogenous default and made several major contributions. It was one of the first structural credit models to define default endogenously as the point at which a firm will no longer be able to raise capital to meet its forthcoming debt obligations. It was also the first structural credit risk model that allowed for coupon-paying debt, multiple classes of debt, and default to occur before maturity. The fact that, in the Geske model, default occurs at discrete points in time can be viewed as both a positive and a negative: it is actually realistic since defaults do typically occur when a major payment is due and not made; but with a large number of cash flows this becomes computationally inefficient. Furthermore, the fact that in the Geske model the firm is systematically de-leveraging is typically viewed as a negative feature. Essentially, this assumption implies that if the firm never defaults it will eventually have an all-equity capital structure.

The Leland (1994) model and its successor the Leland and Toft (1996) model represents the standard up to which all modern structural credit risk models are now held. The Leland and Toft (1996) model has a flat, endogenously

---

[10] Typically the KMV model is used to estimate 1-year default probabilities, since it follows a European option setup. However, it is not uncommon for researchers to synthetically construct an ad-hoc default probability curve so as to allow for direct comparison between the KMV model and the barrier and compound option structural credit risk models which do give default probabilities over time.

[11] Acharya and Carpenter (2002), not discussed here, have a structural credit risk model with endogenous default and stochastic interest rates.

[12] Schaefer and Strebulaev (2006) study capital structure arbitrage within the context of structural credit risk models. This is also discussed in Schaefer and Strebulaev (2008).

determined default barrier. Also, since the model includes corporate taxes and bankruptcy costs it jointly values corporate securities and solves for the optimal capital structure. It also gives default probabilities for varying debt maturities. Leland (2004) compares default probabilities generated by the Longstaff and Schwartz (1995) exogenous barrier model with those generated by the Leland and Toft (1996) endogenous barrier model, and finds that the Longstaff-Schwartz model does not give reasonable default probabilities or recovery rates except when the parameters are chosen so that the default barrier coincides with the endogenous barrier solved by the Leland-Toft model.

Arbitrage Opportunity Set and the Role of Corporations

James S. Ang and Yingmei Cheng

Abstract

We show that capital asset markets are made more efficient when investors and corporations could both engage in arbitrage. Previously known limits to arbitrage by investors are mitigated by explicitly recognizing the role of corporations as arbitragers. We derive the equilibrium regimes in which the dominant arbitrageurs in the capital markets are the investors, the corporations, both, or neither. Corporations enlarge the arbitrage opportunity set as they have several unique properties that could not be replicated by investors as arbitragers. We suggest that the desire to exploit arbitrage opportunities infeasible to investors could provide a new explanation for the formation of corporations.

Keywords

Corporate arbitrage • Investor arbitrage • Limits to arbitrage

57.1 Introduction

Arbitrage serves a critical role in the functioning of efficient capital markets. Viable arbitrage keeps the market prices of securities close to their fundamental values, and allows speedy asset price adjustment to new information. However, there are well-documented costs and risks to investors engaging in arbitrage. They range from information and transaction costs (Merton, 1987) to fundamental risk and noise trader risk (Campbell and Kyle, 1993; Shleifer and Vishny, 1997). Limits to arbitrage by investors may prevent them from engaging in some arbitrage opportunities. If there were no alternatives to arbitrage by investors, market prices for some securities may deviate from their fundamental values for a sustained period (Shleifer, 2000).

In this chapter, we demonstrate that corporations serve a useful function by stepping in to fill the role of arbitrageurs in many instances that the investors find infeasible or unprofitable. They can do so because the corporate form affords them certain advantages over investors in conducting arbitrages. Corporations can purchase mispriced assets in bulk and take possession of the control rights. These are essential to exploit arbitrage opportunities that are not available to the investors. Bulk purchase is required when the opportunity involves privately held businesses. Moreover, having control right enables the corporation to restructure (divide, repackage, and sell) all or same of the assets of both private and public companies. Another principal advantage lies in the corporations' ability to create the short side of the arbitrage transaction by issuing and thus, shorting, their own securities. For instance, having identified an undervalued firm, an acquirer, as a corporate arbitrageur, can effectively construct an arbitrage position by acquiring the undervalued firm, and using its own stocks in exchange, i.e., shorting its own stocks. In contrast, the investors need to secure the short securities from third parties, incurring search and carrying costs. These differences suggest that corporations should be more capable of arbitraging long horizon mispricing, a shortcoming of investor arbitrage as pointed out by Shleifer and Vishny (1990).

Our analysis proceeds at two levels. We first model the technical aspects of putting together an arbitrage position by investors versus by corporations, such as carrying costs, purchase premium, fees and transaction costs, and the risk

of early liquidation. The model yields an equilibrium frame-work delineating regimes in which dominant arbitrageurs responsible for market efficiency are identified. In the second part of the analysis, we show that, due to certain properties of the corporate form, there are types of market inefficiency that only corporations can exploit. Corporations expand the feasible corporate opportunity set, and thus, reduce the size and duration of inefficient asset pricing. Arbitrage by corporations complements arbitrage by investors. Investors may arbitrage away mispriced securities that involve relatively low transaction costs and short investment horizon. Corporations, on the hand, can do the 'heavy lifting': they engage in lumpier and longer term bets that investors avoid.

The contributions of this chapter are threefold. The first is to show that corporate arbitrage could be instrumental in keeping asset prices within tighter bounds of their long-term values. It helps us to understand better how capital markets achieve long-term efficiency. The second is to provide another rationale for the formation of corporations. Investors may get together to form corporations in order to conduct profitable arbitrages, since corporate arbitrage can be more feasible than the investor arbitrage under certain circumstances. The third is to shed new light on a good number of corporate policies and practices by interpreting them as attempts to conduct corporate arbitrage on mispriced assets. The examples range from acquisitions (Gonzales et al., 1998; Mandelbaum, 1995 and DeBondt and Thompson, 1992), to restructuring involving major organizational changes such as bust up, buyout and spin off, to the timing and selection of different types of financing, and to the demand for financial innovations.

The remainder of the chapter is organized as follows. Section 57.2 reviews the literature on the limits to arbitrage. To compare investor and corporate arbitrage, we model, in Section 57.3, investors as arbitragers versus as shareholders of corporations engaging in arbitrage. We show that even under similar conditions, there exist a set of parameter values (circumstances) in which corporate arbitrage is profitable while investor arbitrage is not. Section 57.4 analyzes the types of arbitrage opportunities that are more likely to be exploited by corporations than by individuals. Section 57.5 discusses the implications of corporate arbitrage in the practice of corporate finance. Section 57.6 summarizes and concludes.

57.2 Limits to Investor Arbitrage

The classic definition of arbitrage requires that the arbitrageur be able to identify a mispriced security and its perfectly correlated counterpart, and take a long or short position in the mispriced security and an opposite position in its counterpart at zero net cost. These ideal conditions are generally conceded not to be attainable. There are costs and risks ranging from information and transaction costs (Merton, 1987) to fundamental risk and noise trader risk (Campbell and Kyle, 1993; Shleifer and Vishny, 1997).

There are a number of papers that focus on the financial constraints faced by investor arbitrageurs. In Tuckman and Vila (1992), financial constraints can arise from holding costs. In Dow and Gorton (1994), financial constraints take the form of short horizon and trading costs. Shleifer and Vishny (1997) emphasize a wealth constraint in which money managers' arbitrage operation depends on the availability of external funds whose inflow is sensitive to the managers' performance. Gromb and Vayanos (2002) model financial constraints to arbitrageurs in the form of liquidation risks.[1] DeLong, Shleifer, Summers and Waldmann (1990) attribute limited arbitrage to noise trader risks and short horizons of risk-averse arbitrageurs. In Shleifer and Vishny (1992), investor arbitragers have short horizon, because the risks of adverse price movements and forced liquidation increase with holding period. Barberis and Thaler (2002) caution that there may not be a close substitute for the mispriced security. Wurgler and Zhuravskaya (2002) find that for stocks without close substitutes, arbitrage is weaker and mispricing is more frequent and severe. There is also the synchronization risk among arbitrageurs to affect price adjustments (Abreu and Brunnermeier, 2002).

Short selling can be restrictive and costly (for example, D'Avolio, 2002; Jones and Lamont, 2002; Lamont and Thaler, 2003). First, institutional restrictions and cultural bias limit short selling, for instance, Almazan, Brown, Carlson and Chapman (2004) document that although 30% of mutual funds are allowed to short, only 2% actually do. Lamont (2003) also finds that firms take actions to impede short selling. Second, the search for a stock lender could be costly and time consuming (Duffie et al., 2002). Third, short sellers are required to post additional collateral if prices rise (Mitchell et al., 2002). Fourth, stock loans are subject to recall risks, as the stocks that are being shorted may have to be returned to the lenders on demand. Short sellers may have to close their position and suffer a loss if they cannot find another lender. Finally, the security lending market can be illiquid (Ofek et al., 2004). The practical limits to short selling are reflected in the paucity of the number and frequency of actual short sales. Dechow, Hutton, and Meulbroek (2001) find evidence of few short sales: in 1976–1993, among stocks in NYSE (AMEX), 80% (90%) have less than 0.5% (5%) short to shares outstanding. In an international study, Bris, Goetzmann, and Zhu (2007) find markets that are more constrained for short sales have higher volatility and less informational efficiency.

---

[1] For example, collateral value in a margin account becomes negative.

To summarize, we find a burgeoning theoretical and empirical research in the economics and finance literatures recognizing the limits to arbitrage by investors. There are, however, still several important questions that have to be addressed: Are there alternatives to arbitrage by investors? When are corporations better at exploiting mispricing in the capital markets? What about stocks that investor arbitrageurs avoid: will their share prices be inefficient for prolonged periods, once they deviate from equilibrium? Is there a pricing bound to long term mispricing? In Section 57.4, we shall present arguments that corporations could fill the role of arbitrageurs in situations investors find infeasible. Corporate arbitrage would expand the set of arbitrage opportunities, and reduce the range of price inefficiency among long horizon assets. We compare arbitrage by investors versus by corporations at two levels: investors as arbitragers against shareholders of the corporations engaging in arbitrage (in Section 57.3), and against the corporations conducting arbitrage (in Section 57.4).

57.3 The Model

In the analysis to follow, we model the risk that prevents investors from committing to long horizon arbitrage: adverse price movement caused by noise traders that may result in premature liquidation. Since the risk of premature liquidation to investor arbitragers is related to their levered position and the associated risk of margin call in the interim periods, we endow investor arbitragers and shareholders of corporations engaging in arbitrage with the same amount of margined debt, to enable equitable comparison. The model below derives the arbitrage opportunity set for these two types of arbitrageurs. The size of the arbitrage opportunity set, being a function of the minimum mispricing for the arbitrage to be feasible, also gives a measure of the bounds on market inefficiency.

Here, we choose to model the case when the arbitrage opportunity is an undervalued asset/firm. It provides for potentially more interesting analysis as it involves more contending parties, with transactions that are harder to be replicated by the investors. The analysis of the opposite case of arbitrage opportunities involving overvalued assets is straightforward. (See footnote below).[2]

In the model, there are three dates, 0, 1 and 2. Date 0 is the starting time, when the noise trader may cause the stock of the firm to be mispriced, thus presenting an arbitrage opportunity. Date 1 is the intermediate period in which noise traders may cause the stock price to either diverge further away, or get closer to its fair value. Date 2 is the final time period in which asset price converges to its fair price, i.e., all uncertainties about pricing are resolved on this date.

Although the basic setting simplifies a multi-period model, the period between date 1 and date 2 may be long in practice, for example, several years. For the sake of simplicity, every agent in the model is assumed to be risk neural.

57.3.1 Investor Arbitrageurs

In this basic model of investor arbitrageurs who face noise trader risks, we follow Shleifer and Vishny (1990) and Campbell and Kyle (1993) closely. The set of agents are: the investor arbitrageurs, the noise traders, and a firm with traded shares. Let V_t be the firm's fair value, and P_0 be its stock price at period 0. We assume the supply of shares is one unit. For simplicity, we further assume the mispriced firm's capital structure is made up of 100% equity.

At date 0, noise traders are pessimistic about the value of the firm, where α is the dollar size of the pessimistic shock. The quantity of the firm's equity demanded by the noise traders can be written as:

$$q(noise) = (V_t - \alpha)/P_0 \qquad (57.1)$$

To the potential arbitrageurs, undervaluation of magnitude α gives rise to an arbitrage opportunity. To implement the arbitrage strategy, the investor arbitrageurs take a long dollar position of B in the stock of the undervalued firm at time 0. B is endogenously determined by the investor's maximization problem, as derived below. The quantity of the undervalued firm's equity demanded by the arbitrageurs is:

$$q(arbitrageurs) = B/P_0 \qquad (57.2)$$

Because of unit stock supply, we have

$$P_0 = V_t - \alpha + B \qquad (57.3)$$

To finance the arbitrage position of B dollars, the arbitrageurs need to short a similar security of equal

---

[2] The corporate arbitrageurs can arrange for a spinoff of their overvalued assets as independent legal entities, through IPOs to outside investors. The best-known example of exploiting an overvalued corporate asset is when 3Com spun off the overvalued Palm Pilot resulting in a valuation of Palm Pilot greater than that of its majority parent. They can also split off the overvalued assets and distribute pro rata shares of the new entities to existing shareholders. Finally, they can simply sell the overvalued asset to a willing buyer. Although investors can also sell shares of overvalued stocks they own, because they must hold diversified portfolios, potential gain from a single or few securities is small. Furthermore, information cost to uncover mispricing out of a portfolio with many stocks may reduce if not eliminate potential profits. The remaining question of how a firm comes upon overvalued asset is discussed in Section 57.5.

amount. Let us call the security on the short side, S. Security S is highly but not perfectly correlated with the undervalued firm's security. For instance, they may be related to each other by many fundamental factors, but may not be affected by noise traders in the same way.[3] Let net implementation cost for shorting security S be $B((1 + R)^n\text{-}1)$, where n is the number of periods. For simplicity, we assume the risk-free interest rate is zero, thus R reflects the implementation cost for the investors to short the security. At date 1, the noise traders mistakenly identifying some noise as a fundamental change and deliver another shock, γ. The shock is evenly distributed between $-(V_t - \alpha)$ and $+\alpha$. That is, at date 1, the value of the firm, $V_t - \alpha + \gamma$ falls between 0 and V_t. The shock, even an optimistic one, is assumed not to be large enough to bring the security's market price back to its fundamental value at date 1. The distribution function of γ is $f(\gamma) = \frac{1}{V_t}$. To simplify, we shall assume the short security, S, has no noise trader risk at date 1, or that γ is net of common price variations between the two securities.[4] We model noise trader risk as follows: when the arbitrageurs' asset value falls below a critical percentage of the original level, a margin call will be issued,[5] and the arbitrageur will have to liquidate prematurely at date 1. Let k denote the critical level, where $k \in (0, 1)$. Given the firm's value is $V_t - \alpha$, the shock at date 1, γ, has to cause a price decline large enough to trigger a margin call, i.e., γ is negative and has a magnitude greater than or equal to $(1\text{-}k)(V_t\text{-}\alpha)$. If a margin call is issued, the arbitrageurs liquidate prematurely, and receive $(V_t - \alpha + \gamma) * (B/P_0)$. Otherwise, the arbitrageurs need to take no action at date 1, and will reach date 2 to receive final payoff of $V_t * (B/P_0)$. The arbitrageurs choose the optimal position size B by solving the following problem at date 0:

$$\underset{B>0}{Max} \frac{1}{1+R} \int_{-(V_t-\alpha)}^{-(1-k)(V_t-\alpha)} \frac{B}{P_0}(V_t - \alpha + \gamma)f(\gamma)d\gamma$$

$$+ \frac{1}{(1+R)^2} \int_{-(1-k)(V_t-\alpha)}^{\alpha} \frac{B}{P_0}V_t f(\gamma)d\gamma - B \qquad (57.4)$$

$$P_0 = V_t - \alpha + B.$$

That is, $\underset{B>0}{Max} \frac{1}{1+R} \frac{B}{V_t-\alpha+B} \frac{1}{V_t}\left[\frac{1}{2}k^2(V_t-\alpha)^2\right]$.

The endogenous nature of B is made evident by an examination of the above expressions. Increasing stake in the arbitrage position B, would lead to higher current price, P_0, and thus, higher cost basis and beyond a certain point, lower profit for the arbitragers. The optimization problem may be interpreted as finding the optimal level of arbitrage activity by balancing the positive effect of B on profit due to size of the position, against the negative effect of B on investors' cost basis, while taking into account of premature liquidation. Net liquidation loss to the investors at date 1 increases with B.

The first order condition is:

$$\frac{V_t - \alpha}{(V_t - \alpha + B)^2} \cdot W = 1, \qquad (57.5)$$

where $W = \frac{1}{1+R} \frac{1}{2V_t} k^2(V_t - \alpha)^2 + \frac{\alpha+(1-k)(V_t-\alpha)}{(1+R)^2}$.

Solving Equation 57.5, we have

$$B^* = \begin{cases} \sqrt{(V_t - \alpha)W} - V_t + \alpha, & if \sqrt{(V_t - \alpha)W} - V_t + \alpha > 0 \\ 0, & otherwise \end{cases},$$

$$(57.6)$$

Proposition 1 *Arbitrage by investors is feasible if and only if $\alpha \geq \alpha_0$, where,*

$$\alpha_0 \equiv \frac{-\left[(1+R)^2 + k - (1+R)k^2\right] + \sqrt{\left[(1+R)^2 + k - (1+R)k^2\right]^2 + 2k^2(1+R)\left(-\frac{1}{2}(1+R)k^2 - (1-k) + (1+R)^2\right)}}{(1+R)k^2} \cdot V_t$$

and α_0 is a positive number.

The proof is in Appendix A.

---

[3] Otherwise, the arbitrage position is perfect, and there is no risk, including that of premature liquidation.

[4] An alternate assumption is to let B be a loan, which will not experience noise trader risk.

[5] Another interesting complication in the literature is to allow arbitrageurs to invest more funds in the mispriced asset if it shall further deviate from its fair value, i.e., when there is a negative price shock at date 1, there are cash reserves to meet margin call and to commit more

investments. However, the risk of this trading strategy increases as the number of periods, N, increases, as discussed in Section 57.5.

The intuition behind Proposition 1 is straightforward: the minimum magnitude of mispricing for the arbitrage to be profitable has to be large enough to offset the cost of implementing the position, and the risk of adverse price change at date 1. Alternatively, one may interpret $\alpha - \alpha_0$ as the size of the arbitrage opportunity set to investors, and the minimum value of α, i.e., α_0, gives the range of admissible market inefficiency, where there is no investor arbitrage activity to eliminate mispricing.

Proposition 2 *Arbitrage by investors on mispriced securities is less than complete, i.e., it will not be enough to completely eliminate the amount of mispricing at date 0.*

Proof It is straightforward to verify that $B^* < \alpha$, i.e., $V_0 = V_t - \alpha + B < V_t$ at date 0. The details are in Appendix A.

Because $P_0 = V_t - \alpha + B$, we have

$$P_0^* = \sqrt{(V_t - \alpha)W} \qquad (57.7)$$

Equation 57.7 gives the equilibrium price at date 0, after investor arbitrageurs have completed their trading position.

Corollary 1 *At the optimal arbitrage position B, the expected payoff to the investor arbitrageurs is $\Lambda = \left[\sqrt{V_t - \alpha} - \sqrt{W}\right]^2$.*
The proof is in Appendix A.

57.3.2 Shareholders of Corporations Engaging in Arbitrage

In this section we analyze the same set of issues (risk of liquidation, size of arbitrage opportunity set, admissible market efficiency, arbitrage profit) to shareholders of corporations engaging in arbitrage. Let V_0 be the market value of an undervalued firm, T, at date 0. A corporation A may recognize that firm T is underpriced, and construct an arbitrage position by paying a non negative premium (ρ) to acquire (long) all the stocks at $V_0 + \rho$, with its own stocks (the short component). The process may be described by the following time line: the acquirer proposes a merger and offers premium (ρ) at date 0, and the merger is completed before date 1 if the target accepts the merger offer at date 0. For simplicity, let us assume the capital structures of both the acquirer and the target are made up of 100% equity.

We analyze corporate arbitrage under the same set of circumstances as in Section 57.3.1. At date 0, firm T is underpriced by the amount α, that is: $V_0 = V_t - \alpha$. Misvaluation is to be resolved at date 2. At date 1, the noise traders, responding to a noise that is mistaken as a fundamental change, could cause the share price of firm T to change. The noise parameter γ has the same distribution as modeled in Section 57.3.1. Corporate arbitrageurs, in the first half of the arbitrage transaction, may take advantage of the opportunity by making an offer to firm T, now

designated as the target firm. The shareholders of the target firms have two choices: to accept or reject the offer. If the target does not accept the premium offered by the acquirer, the target shareholders may get the margin call at date 1 if $V_t - \alpha + \gamma$ is less than $k(V_t - \alpha)$. Otherwise, the target shareholders hold the stocks until date 2 and receive the value V_t, since the target firm's undervaluation of α is corrected at date 2, i.e., $(V_t - \alpha) + \alpha = V_t$. The target's management is fully aware of size and timing of its mispricing α. That is, the expected payoff of the shareholders of the potential target, if not acquired, is

$$\int_{-(V_t - \alpha)}^{-(1-k)(V_t - \alpha)} (V_t - \alpha + \gamma)f(\gamma)d\gamma + \int_{-(1-k)(V_t - \alpha)}^{\alpha} V_t f(\gamma)d\gamma \qquad (57.8)$$

$$= \frac{1}{2}k^2\frac{(V_t - \alpha)^2}{V_t} + (1-k)V_t + \alpha k$$

The first term in Equation 57.8 is the payoff in case of early liquidation, and the second term is the payoff of no early liquidation. If the target shareholders choose instead to accept the premium offered by the acquirer, we allow the same shock to the target's stock to affect share price of the merged firm, thus, cause the share price of the merged firm to decline by the same amount, that is, the value of the combined firm at date 1 is $V_a + V_t - \alpha + \gamma$, where V_a is the acquirer's value.[6] If $V_a + V_t - \alpha + \gamma < k(V_a + V_t - \alpha)$, then the shareholders of the merged firm, too, receive the margin call. At date 2, the value of the merged firm, V_c, is the combination of the target's value, the acquirer's value and the incremental value Ω. That is, $V_c = V_a + V_t + \Omega$. Similar to correction from mispricing, α, the post merger incremental value Ω, is not to be realized until date 2. Ω can be positive or negative.

The shock, γ, is evenly distributed between $-(V_t - \alpha)$ and $+\alpha$. If $k < \frac{V_a}{V_a + V_t - \alpha}$, $V_a + V_t - \alpha + \gamma$ will always be greater than $k(V_a + V_t - \alpha)$. In this case, the risk of early liquidation does not exist for the shareholders of the combined firm. To consider the liquidation risk in the following analysis, we assume $k \geq \frac{V_a}{V_a + V_t - \alpha}$. The quantity in the right hand side is a function of the relative size of the acquirer to the pre revaluation combined value of the merged firm. That is, the effect of noise risk depends on the ability of the

---

[6] Implicit in this formulation is that noise is a perturbation disguised as pricing factor that is capable of affecting share prices of the merged firm. The other way to model noise is to attribute mispricing from irrational trading of the target's shares by the noise traders. The latter case works in favor of corporate arbitrage since noise traders, not being able to trade in the now acquired target's shares, would not have any impact.

merged firm to absorb the shock. The results and the main conclusions will only become stronger in the case of $k < \frac{V_a}{V_a + V_t - \alpha}$, the analysis is presented in Appendix B.

The target shareholders' expected payoff, in a stock for stock exchange, from the acquisition, is[7]:

$$\int_{-(V_t - \alpha)}^{-(1-k)(V_a + V_t - \alpha)} \frac{V_t - \alpha + \rho}{V_a + V_t - \alpha}(V_a + V_t - \alpha + \gamma)f(\gamma)d\gamma$$
$$+ \int_{-(1-k)(V_a + V_t - \alpha)}^{\alpha} \frac{V_t - \alpha + \rho}{V_a + V_t - \alpha}(V_a + V_t + \Omega)f(\gamma)d\gamma$$

(57.9)

We can rewrite Equation 57.9 as $\frac{V_t - \alpha + \rho}{V_t(V_a + V_t - \alpha)} \cdot C$, where $C = \frac{1}{2}[(V_a + V_t)(1 - k) + \alpha k]^2 + \frac{1}{2}V_t^2 + V_a V_t + \Omega((V_a + V_t)(1 - k) + \alpha k)$

C is positive as long as

$$\Omega > -\frac{\frac{1}{2}[(V_a + V_t)(1 - k) + \alpha k]^2 + \frac{1}{2}V_t^2 + V_a V_t}{(V_a + V_t)(1 - k) + \alpha k}. \quad (57.10)$$

Let us assume for convenience that Equation 57.10 holds for now, which we will see later that this constraint is not binding.

The target's shareholders will accept the offer if

$$\frac{V_t - \alpha + \rho}{V_t(V_a + V_t - \alpha)} \cdot C \geq \frac{1}{2}k^2 \frac{(V_t - \alpha)^2}{V_t} + (1 - k)V_t + \alpha k$$

(57.11)

i.e., the premium ρ has to satisfy the following:

$$\rho \geq \alpha - V_t + \frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1 - k)V_t^2 + \alpha k V_t}{C} \cdot (V_a + V_t - \alpha)$$

(57.12)

Because C increases in Ω, the minimum premium demanded by the target decreases in Ω. That is, a rational target would tradeoff merger premium and share of post merger expected gain in a stock for stock exchange; he higher the post merger gain is, the lower is the premium demanded by the target. We restrict the premium to be nonnegative, therefore the target demands the premium as, $\rho \geq \max(\alpha - V_t + \frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha k V_t}{C}(V_a + V_t - \alpha), 0)$. That is, (1) if $\alpha - V_t + \frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha k V_t}{C}(V_a + V_t - \alpha) \geq 0$, the target demands the premium $\rho \geq \alpha - V_t + \frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha k V_t}{C}$.

$(V_a + V_t - \alpha)$; (2) if $\alpha - V_t + \frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha k V_t}{C}(V_a + V_t - \alpha) < 0$, the target demand the premium of 0. $\alpha - V_t + \frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha k V_t}{C}(V_a + V_t - \alpha) \geq 0$ is equivalent to $\Omega \leq \frac{\frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha k V_t}{V_t - \alpha}(V_a + V_t - \alpha) - \frac{1}{2}[(V_a + V_t)(1-k) + \alpha k]^2 - \frac{1}{2}V_t^2 - V_a V_t}{(V_a + V_t)(1-k) + \alpha k}$. Let us denote $\frac{\frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha k V_t}{V_t - \alpha}(V_a + V_t - \alpha) - \frac{1}{2}[(V_a + V_t)(1-k) + \alpha k]^2 - \frac{1}{2}V_t^2 - V_a V_t}{(V_a + V_t)(1-k) + \alpha k}$ as Ω_0.

The acquirer shareholder's expected value, in a stock for stock exchange, at date 2 is:

$$\int_{-(V_t - \alpha)}^{-(1-k)(V_a + V_t - \alpha)} \frac{V_a - \rho}{V_a + V_t - \alpha}(V_a + V_t - \alpha + \gamma)f(\gamma)d\gamma$$
$$+ \int_{-(1-k)(V_a + V_t - \alpha)}^{\alpha} \frac{V_a - \rho}{V_a + V_t - \alpha}(V_a + V_t + \Omega)f(\gamma)d\gamma - \phi$$

(57.13)

We can rewrite Equation 57.13 as $\frac{V_a - \rho}{V_t(V_a + V_t - \alpha)} \cdot C - \phi$. ϕ is the acquirer's merger cost excluding the premium, for example, investment banking fees. ϕ is a positive number.

The acquirer shareholder's expected value, without the acquisition, at date 2 is V_a. Therefore, the acquirer will make the arbitrage motivated acquisition if

$$\frac{V_a - \rho}{V_t(V_a + V_t - \alpha)} \cdot C - \phi \geq V_a \quad (57.14)$$

That is, $\rho \leq V_a - \frac{(V_a + \phi)V_t}{C}(V_a + V_t - \alpha)$.

Because the premium is restricted to be nonnegative, the acquirer offers the following premium schedule:

If $V_a - \frac{(V_a + \phi)V_t}{C}(V_a + V_t - \alpha) > 0$, then $\rho \in [0, V_a - \frac{(V_a + \phi)V_t}{C}(V_a + V_t - \alpha)]$;

If $V_a - \frac{(V_a + \phi)V_t}{C}(V_a + V_t - \alpha) = 0$, then $\rho = 0$.

Proposition 3 *The necessary condition for the merger to be feasible is that* $V_a - \frac{(V_a + \phi)V_t}{C}(V_a + V_t - \alpha) \geq 0$. *That is,*

$$\Omega \geq \frac{\frac{(V_a + \phi)V_t}{V_a}(V_a + V_t - \alpha) - \frac{1}{2}[(V_a + V_t)(1 - k) + \alpha k]^2 - \frac{1}{2}V_t^2 - V_a V_t}{(V_a + V_t)(1 - k) + \alpha k}.$$

(57.15)

Proof If $V_a - \frac{(V_a + \phi)V_t}{C}(V_a + V_t - \alpha) < 0$, then the premium the acquirer is willing to offer has to be below zero, which violates the nonnegative premium constraint. Thus the merger is not feasible in that case.

Let us denote $\frac{\frac{(V_a + \phi)V_t}{V_a}(V_a + V_t - \alpha) - \frac{1}{2}[(V_a + V_t)(1-k) + \alpha k]^2 - \frac{1}{2}V_t^2 - V_a V_t}{(V_a + V_t)(1-k) + \alpha k}$ as Ω_1. Ω_1 is a decreasing function of α. That is, the higher is the magnitude of undervaluation, the lower is the minimum value of post merger gain that is necessary for the acquirer to participate in the merger. Equation 57.15 implies

---

[7] The following formulation assumes the market attributes no gain to the merger at announcement, and the post announcement prices form the basis for the exchange ratio.

Table 57.1 Equilibrium regimes of dominant arbitrageurs

	$\Omega < \Omega_1$	$\Omega \geq \Omega_1$, and $\Omega \geq \Omega_0$	$\Omega \geq \Omega_1$, and $\Omega < \Omega_0$
$\alpha < \alpha_0$, and $\alpha < \alpha_1$	Neither	Corporations	Not applicable[a]
$\alpha < \alpha_0$, and $\alpha > \alpha_1$	Neither	Corporations	Corporations if $\Omega \geq \Omega_2$
$\alpha > \alpha_0$, and $\alpha < \alpha_1$	Investors	Corporations, and investors	Not applicable[a]
$\alpha > \alpha_0$, and $\alpha > \alpha_1$	Investors	Corporations, and investors	Corporations if $\Omega \geq \Omega_2$; and investors

[a]"$\Omega \geq \Omega_1$, and $\Omega < \Omega_0$" requires that $\alpha > \alpha_1$

$$\alpha_0 \equiv \frac{-\left[(1+R)^2+k-(1+R)k^2\right]+\sqrt{\left[(1+R)^2+k-(1+R)k^2\right]^2+2k^2(1+R)\left(-\frac{1}{2}(1+R)k^2-(1-k)+(1+R)^2\right)}}{(1+R)k^2} \cdot V_t$$

$$\text{and } \alpha_1 = \frac{-\left[(V_a+\phi)V_t-k^2V_aV_t\right]+\sqrt{\left[(V_a+\phi)V_t-k^2V_aV_t\right]^2+2k^2\alpha^2V_a(kV_aV_t^2-\frac{1}{2}k^2V_aV_t^2+\phi V_t^2)}}{V_ak^2}$$

that the assumption in Equation 57.10 is not binding, as we mentioned before.

Proposition 4 *Given $\Omega \geq \Omega_1$, if $\Omega \geq \Omega_0$, the merger is feasible. Given $\Omega \geq \Omega_1$, if $\Omega < \Omega_0$, the merger is still feasible as long as $\Omega \geq \Omega_2 \equiv \frac{-\frac{1}{2}V_a^2(1-k)^2-V_aV_t(1-k)^2-\alpha V_ak(1-k)+\phi V_t}{(1-k)(V_a+V_t)+\alpha k}$.*

The proof is in Appendix A.

Proposition 5 *The merger premium, ρ_0, is less than the magnitude of misvaluation, α, if $\Omega > \Omega_3$, where Ω_3 is a negative number and*

$$\Omega_3 = \frac{-(\frac{1}{2}\alpha V_t^2+\frac{1}{2}V_a^2V_t+\frac{1}{2}V_aV_t^2)(1-k)^2-k\alpha^2V_t(1-k)-\frac{1}{2}(V_aV_t^2-V_a\alpha^2k^2+\alpha^3k^2+\alpha V_t^2)}{V_t((V_a+V_t)(1-k)+\alpha k)}.$$

The proof is in Appendix A.

Proposition 5 shows that when acquisition with premium is feasible for corporate arbitrageurs, the acquirer needs not give up all of arbitrage profit stemming from target's undervaluation in the form of premium, as long as the post merger gain is above a certain level.

In the equilibrium, the acquirer pays the minimum premium demanded by the target, i.e.,

$$\rho_0 = \max(\alpha - V_t + \frac{\frac{1}{2}k^2(V_t-\alpha)^2+(1-k)V_t^2+\alpha kV_t}{C}$$
$$(V_a+V_t-\alpha), 0)$$
(57.16)

We can derive the arbitrage profit for the shareholders of corporate acquirer as:

$$\frac{V_a-\rho}{V_t(V_a+V_t-\alpha)} \cdot C - \phi - V_a$$
$$= \min\left(\frac{C-\frac{1}{2}k^2(V_t-\alpha)^2-(1-k)V_t^2-\alpha kV_t}{V_t}\right.$$
$$\left. - \phi - V_a, \frac{V_a}{V_t(V_a+V_t-\alpha)} \cdot C - \phi - V_a\right)$$
(57.17)

Corollary 2 *For any magnitude of undervaluation, α, the merger is feasible as long as $\Omega \geq \max(\Omega_1,\Omega_0)$; when $\alpha \geq \alpha_1$, the merger is also feasible as long as $\Omega \geq \frac{-\frac{1}{2}V_a^2(1-k)^2-V_aV_t(1-k)^2-\alpha V_ak(1-k)+\phi V_t}{(1-k)(V_a+V_t)+\alpha k}$, where*

$$\alpha_1 = \frac{-\left[(V_a+\phi)V_t-k^2V_aV_t\right]+\sqrt{\left[(V_a+\phi)V_t-k^2V_aV_t\right]^2+2k^2V_a(kV_aV_t^2-\frac{1}{2}k^2V_aV_t^2+\phi V_t^2)}}{V_ak^2}.$$

The proof is in Appendix A.

Proposition 4 and Corollary 2 demonstrate that regardless of the magnitude of misvaluation, α, the merger is feasible if the post merger gain, Ω, is above a certain level. Base on the results we obtained so far, we can specify the sets of parameters under which the investor and/or corporate arbitrage may be feasible.

Table 57.1 shows that there are four possible equilibria in different regimes: investors only, corporations only, both investors and corporations, and neither type. These regimes are classified on basis of two sets of parameters: the size of

original pre arbitrage opportunity, and the size of post arbitrage (or merger) gains. In presence of large mispricing but low post merger gain, investor arbitrage is favored. But corporate arbitrage is feasible, regardless of target's mispricing, if post merger gain is higher than a certain level, e.g., $\Omega \geq \max(\Omega_1, \Omega_0)$. In regimes admitting both types of arbitrageurs, several scenarios may be possible: one is that the investor arbitrageurs would initiate arbitrage position to put the target in play, or to flush out potential acquirers; another is that the investor arbitrageurs engage in the arbitrage after an acquisition is announced but the probability of the merger to reach completion is highly uncertain.[8] Finally, there exists a regime in which neither investors nor corporations could engage in arbitrage, and market may remain inefficient. In this regime, the pre-merger undervaluation is small and the post-merger gain is low.

Both the traditional and behavioral finance literatures recognize that limits to arbitrage for individuals and institutions may provide the reasons for well-documented instances of market failures, e.g., market anomalies and price bubbles. Since both risks and costs of an arbitrage position increase with time, limits to arbitrage are especially severe when the period to mispricing correction is long (Shleifer and Vishny, 1990). The period of apparent inefficiency may increase with the time needed to reveal information.

57.4 Expanding the Arbitrage Opportunity Set by Corporations

Up to this point, we limit our analysis to arbitrage opportunities that are available to both investors and corporations, with emphasis on the technical aspects of putting together an arbitrage position by investors versus by corporations, such as carrying costs, purchase premium, availability and cost of the short position, and the risk of early liquidation. The analysis is necessary as it enable us to make comparison between these two alternatives under similar circumstances. However, the analysis of arbitrage by corporations is not complete since their arbitrage opportunity set is much larger, i.e., there are situations corporations could arbitrage but investors could not. We shall in this section analyze those corporate arbitrage opportunities, and discuss in the next section the implications of this expanded ability to arbitrage.

An importance difference between an investor and a corporation as an arbitrageur is that the corporation may be able to engage in 'bulk' purchase. With the acquisition of the entire target firm, come the ownership and management rights. These sets of rights are particularly important to unlock the arbitrage profits hidden under some assets. Examples that may involve significant arbitrage gains are provided in the following:

1. When privately held companies are mispriced, they are simply not available to investors.[9] An examination of merger data between 1977 and 2001 (the data source is SDC) indicates that the ratio of the numbers of private targets to public targets is close to 3:2. Although not all such mergers were motivated by arbitrage, but for those that were, it is certain that investor arbitrageurs could not participate.

2. Corporations can purchase the assets in one piece, and create value by fission, i.e., selling parts that are mispriced (Fluck and Lynch, 1999). For example, in "bust up" transactions, the corporate arbitrageurs acquire complete property rights before assets are sold or resold separately.[10]

3. The corporations can also create value by fusion, e.g., purchasing separate assets to form new enterprises. Examples include combining parts of the supply chain to form an integrated company, or acquiring several broadcasting stations to sell them as a national network.[11] Investors simply could not replicate these transactions.

4. Corporate arbitrageurs take control of the misvalued firm, and can influence the timing and size of price corrections. While individual and institutions are by and large passive investors, corporations take an active role in the management of the assets they acquire. Once they acquire complete property right, they can restructure through change in top management, employee layoff, and other cost cutting measures. Furthermore, acquirers could supply the necessary information technology, production skills and facilities, human capital, marketing network, or relatively inexpensive financing for the targets to realize the added value, or synergy. These actions, if effective, would advance the date of price correction.

5. Very substantial information costs are required to identify some of the potential arbitrage opportunities. Corporations, as bulk purchasers, can economize information costs. The ability of the corporate acquirers to conduct "due process" enables them to obtain more accurate information than what the investor arbitrageurs could, and in the case of adverse information, the acquirers can unwind the

---

[8] In the topic of risk arbitrage (see Cornelli and Li, 2002; Mitchell and Pulvino, 2002), investors and corporations may be regarded as arbitrageurs at the same time, with the common goal of seeing the merger completed.

[9] Such information on mispricing may be initiated from an analysis of comparable public companies, as private firms, or their consultants and bankers, as sellers often use valuation of comparable public companies as benchmark in pricing.

[10] Coyne, Fabozzi, and Yaari (1992) have shown how acquisitions may be conducted for asset arbitrage given various business and personal taxes.

[11] There was the case of John Kluge who put together the Metromedia Broadcasting Company that was later sold to become the Fox Network, etc.

position by withdrawing the merger offer. In addition, by purchasing the entire asset, they can avoid high transaction costs from forming and unwinding positions on securities with low liquidity.

The above lists the advantages of corporate arbitrageurs over investor arbitrageurs on the long side. Another set of advantages is associated with the short side of the trading position. Specifically, these are:

1. Firms can short their own stocks by exchanging their own securities for mispriced assets or securities. This is in contrast to investor arbitrageurs having to locate the short securities from third parties and to pay carrying costs. Investor arbitrageurs face a hard constraint when selling borrowed shares: the shares have to be returned at the close of arbitrage position if not sooner. Thus, they have to absorb all the residual risks that are not covered by the arbitrage position. Carrying costs are also mandatory. On the other hand, corporate arbitrageurs face a soft constraint when exchanging their own shares to acquire undervalued assets.[12] There is no legal or compelling requirement for the corporations to settle their positions at a definite date. Further, recipients of the corporate arbitrageurs' securities, who were former target shareholders, have to share the residual risks. Carrying costs, such as dividends, are not mandatory. If both types of arbitrageurs choose to finance their positions with debt, corporate arbitrageurs can shield their shareholders with the limited liability provision, while individuals may risk personal bankruptcy, and institutions may have to contend with institutional or legal restrictions on the use of leverage. As the arbitrage horizon, N, increases, risks as well as other limits to investor arbitrage are magnified by a greater extent than those to corporate arbitrageurs. If noise trader risk could occur in each of the N periods, the overall risk of premature liquidation for investor arbitrageurs increases as N increases. As the number of time period increases, the overall chance that prices of the originally mispriced security may be further away before converging to its eventual fair value is higher.[13] Furthermore, longer time periods would make unattractive, if not eliminate, the strategy of investing even more money when noise trader risk causes another adverse price response in the next period. As the number of periods increases, committing more funds in response to current losses approaches a form of gambler's fallacy, expecting the probability of a favorable reversal to rise. By contrast,

the corporate arbitrageurs/acquirers, not facing the possibility of having to settle up in each period, can afford to be patient.[14]

2. Since firms may issue overvalued securities, corporate arbitrageurs have the unique opportunity to profit from both sides of the arbitrage position. Although investor arbitrageurs may long underpriced securities and short overpriced securities, there are numerous practical difficulties. First, without corporate arbitrageurs' inside informational advantage, investor arbitrageurs would be less likely to identify arbitrage opportunities with potential two-way gains. Second, lenders of short securities, who are long-term holders, may charge a higher carrying cost for overpriced securities. Third, investor arbitrageurs face greater risks, as there is no guarantee that price corrections for both securities would occur at the same time when the trading positions are to close, that is, there is a synchronization risk (Abreu and Brunnermeier, 2002). In contrast, corporate arbitrageurs have more leeway with respect to lack of synchronization in price corrections, since the arbitrageurs do not have to settle at a definite date.

In addition to the synchronization risk mentioned above, investors also face: (1) the inconvenience of recall risk by "short" lenders, in which the replacement has to be found; (2) financing risk, where additional collateral may be needed and thus render the arbitrage no longer a zero investment trading position; (3) horizon risk, i.e., risk of loss from imperfect arbitrage increases with the length of the holding period; (4) fundamental risk, i.e., no arbitrageurs can be certain of the value of the securities; and (5) noise trader risk, as noise traders may cause mispriced securities to diverge further away from their fundamental values. Large blockholders may be able to economize some of the transaction and searching costs, but they still have to find ways to obtain the securities to short, and bear the risks from imperfect arbitrage.[15]

Corporate arbitrageurs, who take the target's shares off the market and create their own short securities by issuing stocks, can avoid synchronization risk, recall risk, and noise

---

[12] We emphasize the word exchange to call attention to the difference between new shares issued to outsiders as in SEOs (secondary equity offers), and an exchange of shares in a merger.

[13] This source of risk increases even further if N is stochastic, thus creating uncertain termination date that could be further confounded with liquidity and synchronization risks.

[14] We acknowledge that certain combination of circumstances such as large cumulative negative price shocks, large target relative to the acquirer, and high correlation between noise trader risks on acquirer's and target's securities can render the combined firm an undervalued and attractive target to other firms. However, this risk should be smaller than the risk of premature liquidation by investor arbitrageurs.

[15] For them to overcome the bulk purchase problem, they need to be able to acquire the decision right via control of the board. That will incur control contest costs, and they have to face free riding cost later on.

trader risk altogether. Financing risk is greatly reduced if the asset acquired is highly correlated with existing assets, such as in horizontal acquisitions.[16]

Fundamental risk could be reduced as corporations have superior information about the targets. Arbitrage trading position is often not riskless, since there are uncertainties concerning the fundamental value of the security in question. The fair value of the security, when finally revealed, may deviate from the value expected at date 0, imposing unknown risks on the arbitrageurs if the short position does not perfectly correlate with the misvalued security. Although both investor arbitrageurs and corporate arbitrageurs are subject to the fundamental risks, the way each type deals with the risk could be different.

Investor arbitrageurs have to settle up at date 2, and suffer the entire loss. Shareholders of the acquirer, however, are able to share some of the loss with the target shareholders who are also stockholders of the same firm. This enables the original shareholders of the corporate arbitrageurs to absorb fundamental risks better than investor arbitrageurs.

Finally, corporations can better absorb horizon risks. They may have lower carrying or financing costs. They are more able to maintain a long holding period as they face less pressure to unwind, and they are more actively involved in the management of the assets to hasten the price correction.

Table 57.2 provides a summary of the main differences between investor arbitrage and corporate arbitrage. Because small investors, in comparison to large individual and institutional investors, are handicapped due to their greater information and transaction costs, the table compares corporate arbitrageurs with only the most efficient investor groups, i.e., large individual and institutional investors. Because of their advantages, firms are capable of expanding the scope of arbitrage opportunities in several ways.

To summarize, these extensions discussed above reinforce the importance of corporate arbitrage, especially when the period of misvaluation correction is long. Since active involvement by the acquiring firms could shorten the time to correct misvaluation, corporate arbitrage helps to facilitate the long-term market efficiency.

57.5 Implications of Corporate Arbitrage

Finally, we consider the implications of corporate arbitrage on the theories and applications of corporate finance. First, there is an implicit assumption in the Modigliani and Miller (M&M) theories: arbitrages by investors and by corporations are equivalent. The classic proof in M&M uses an argument that the individual investors are able to emulate the firm's balance sheet in the personal accounts. As pointed out above, and summarized in Table 57.2, there are arbitrage opportunities that could only be undertaken by the corporate entities. In particular, there are assets, lumpy or in private hands, that only corporations could acquire. In addition, corporations can issue new equities, thus changing their capital structure, to finance the type of arbitrage that investors find infeasible or unprofitable. M&M's emulation strategy breakdowns here as investors could neither acquire the same asset nor duplicate the same capital structure. Thus, when the twin M&M implicit assumptions of efficient capital market pricing, and perfect replication of corporate business and financial policies by investors, are relaxed, we have the following:

A Capital Structure Proposition:

When there arise arbitrage opportunities in which corporations but not investors can exploit, optimal capital structure changes in respond to these opportunities.

Specifically, for the value maximizing firms, (1) arbitrage involving undervalued assets decreases leverage; (2)arbitrage involving overvalued assets may increase or have neutral effect on leverage. Leverage reduces when the firms issue stocks to finance purchase of undervalued assets. Leverage may increase when equity shares are distributed to shareholders in the new entity, or does not change when cash is received from IPO of spin off or outright sale of the overvalued assets, in which cash could retire both debt and equity proportionately.

Since the arbitrage (by investors) mechanism is a cornerstone in the M&M derivations, viable corporate arbitrage, when investor arbitrage fails, is expected to affect their theories as much as the relaxation of their other assumptions, such as no taxes, transaction costs, distress costs, agency problems, and information asymmetry.

Second, if corporate arbitrage can be shown to be more feasible than investor arbitrage in at least some circumstances, the corporate organizational form may be justified from a purely financial standpoint. Rational investors pool their funds together to form corporations in order to exploit arbitrage opportunities that they could not have engaged in by themselves. A special case is a theory of conglomerates, and thus unrelated diversification, in a world in which there exists a positive probability of mispricing in future periods. Without assuming that the firms have the ability to predict

---

[16] It is of interest to note that when a corporate arbitrageur acquires a related company, the cash flows from the stocks of the combined firm offered (the short position) should match the cash flows to be generated from the target's assets. That is, the cash flows from the target's own assets support the stocks received by the target's shareholders. In other words, this type of arbitrage is *self-financing*, satisfying one of the requirements of an ideal arbitrage in which all financing risks to the acquirers should be eliminated.

Table 57.2 A comparison of large investors versus corporate arbitrageurs

	Large investors, including institutions	Corporate arbitrageurs
1. *Arbitrage opportunities involving bulk purchase*	Can only make fractional purchase of traded assets, preferably in liquid markets	Can make bulk purchase
(a) Private firms	No	Yes
(b) Bust up deals or fissions	No	Yes
(c) Create new business entities from parts, or fusions	No	Yes
2. *Identifying, executing and realizing arbitrage opportunities*		
(a) Information costs	Pay same fixed cost	Can spread cost over 100 % of assets
(b) Costs of forming and unwinding illiquid assets	Pay premium to acquire meaningful holding; costs to liquidate could be high	Pay higher premium to acquire 100 %; but exit price may be higher due to transfer of control rights
(c) Ability to affect size and timing of misvaluation correction	None as passive investors, or limited through pressure on management via governance channels	Yes, they can actively restructure operations; incorporate earnings improvement in own financial reports
3. *Ease in obtaining the securities to short*		
(a) Source of "short" securities	Have to borrow shares from willing lenders by incurring searching and carrying costs	Create "homemade short" by issuing own securities
(b) Extra opportunity to arbitrage	None	Possible, can issue own overvalued securities
4. *Dealing with imperfect arbitrage*		
(a) Synchronization risk	Forming and unwinding both the long and short position may not occur at the same time	More flexibility with resolution date, as own stocks have no finite maturity
(b) Recall risk	Yes, an inconvenience in normal period, but could be costly when needed most	None. "Short" investors hold corporation's securities
(c) Financing risk	Collateral in the form of cash and/or securities makes investor arbitrage not a net zero investment strategy. Additional residual risk may be introduced from less than perfect correlation between long and short assets	Small or none, arbitrage is self-financing in all future periods if asset acquired with stocks is highly correlated with own assets
(d) Horizon risk	Risk of loss from imperfection in arbitrage increases with length of time horizon	Greater ability to absorb horizon risk due to a combination of several factors: lower financing costs, active involvement, homemade short, and less pressure to unwind and settle in finite date
(e) Fundamental risk	Could increase unhedged residual risk	May minimize valuation risks if acquisition of undervalued targets from industries where corporate arbitrageur has information advantage
(f) Noise trader risk	Could cause premature liquidation of arbitrage position. Large institutions with diversified portfolio may reduce but cannot eliminate liquidation risks	Noise trader could not affect prices of assets that are taken off the market by corporate acquirer

which stocks may be mispriced in the future, conglomerate firms that started out in time 0 with a collection of unrelated assets know that some assets may be overvalued or undervalued in future periods. For the assets that turn out to be overvalued at a later date, the conglomerate now has overvalued assets to spinoff. And for the assets that turn out to be undervalued in the future, because mispriced assets are small in proportion to the conglomerate's size, the conglomerate structure shields undervalued assets from becoming the targets of acquisition, a fate that is more likely to befall stand alone undervalued firms.

Third, we can rethink various corporate events as instances of corporate arbitrage in situations when investor arbitrage is not possible. These include: overvalued firms acquiring undervalued firms with stocks; firms spinning off or issue as tracking stocks lines of business that are overvalued by the market at the moment; firms issuing overvalued stocks to buy back or retire less overvalued debt; firms issuing stocks to pay dividends and boost stock prices when high dividend paying value stocks are in high demand; firms borrowing at market prices to repurchase undervalued stocks; firms engaging in leverage buyouts by buying the firm's asset and shorting or borrowing outside funds when gross undervaluation occurs; private firms choosing between selling itself to another firm and issuing an IPO (depending on which market is more optimistic – this is an example of arbitrage between real and

capital markets); firms engaging in interest rate and currency swaps (for instance, firms facing high long-term financing rate but low short-term rate can issue short and swap into long-term); and firms forming business alliances, partial ownership arrangements, and cross shareholdings to avoid diversification.

Conclusion

We start with the question: when are corporations better than investors in exploiting mispricing in the capital markets? The arbitrage opportunity sets for both investor and corporate arbitragers are studied in our model. Each arbitrage opportunity set specifies the maximum bounds within which capital assets may not be efficient. Previously known limits to arbitrage by investors are mitigated by explicitly recognizing the role of corporations as arbitragers. Corporations have several desirable properties as arbitragers in dealing with lumpy investments, privately held concerns, those requiring control of property rights, mispricing requiring longer horizon to resolve, etc. The corporate arbitragers also have the ability to minimize the cost and risks of taking the short side and arbitrage.

The theoretical significance of corporations participating in arbitrage is that not only they expand the arbitrage opportunity set and thus, reducing the size of mispricing set, to help facilitate capital markets to be more efficient, but also in the way they influence the quality of market due to the type of assets they choose to arbitrage. With the limitations on the investors' ability to arbitrage, there could be serious deficiencies in the capital markets where large and persistent mispricing may occur for assets that would take time to correct, or effort via restructuring. Corporate arbitrageurs fill this gap, as they can engage in long horizon and lumpy arbitrage.

In our model, we demonstrate that investor arbitrage and corporate arbitrage can both exist. Viable corporate arbitrage complements investor arbitrage in fostering efficient capital market operations. Investor arbitrageurs are known to facilitate market prices toward short-term equilibrium, while we show here that corporate arbitrageurs facilitate toward long-term equilibrium. When noise trader risk or implementation cost is high, and the period of price correction is long, corporate arbitrage is more feasible. Corporate arbitrage provides a new insight into the function of firms. Firms are able to conduct arbitrage in situations where investor arbitrage is not feasible, thus providing a pure financial rationale for the existence of corporation. Many observed corporate financial practices can also be explained as ways to facilitate arbitrage on a large scale, from buying large firms in order to breakup later, to taking firms private, to timing and types of financing, etc.

Appendix A: Proofs of Propositions and Corollaries

A.1. Proof of Proposition 1

Proof $\alpha \geq V_t - \sqrt{(V_t - \alpha)W}$ is equivalent to $V_t - \alpha \leq W$. That is:

$$V_t - \alpha \leq \frac{1}{1+R}\frac{1}{2V_t}k^2(V_t - \alpha)^2 + \frac{\alpha + (1-k)(V_t - \alpha)}{(1+R)^2}.$$

If we collect the terms in the above inequality, we have:

$$\frac{1+R}{2V_t}k^2\alpha^2 + \left[(1+R)^2 + k - (1+R)k^2\right]\alpha + \frac{1+R}{2}k^2V_t$$
$$+ (1-k)V_t - (1+R)^2V_t \geq 0$$

$$\alpha \geq \frac{-\left[(1+R)^2 + k - (1+R)k^2\right] + \sqrt{\left[(1+R)^2 + k - (1+R)k^2\right]^2 + 2k^2(1+R)\left(-\frac{1}{2}(1+R)k^2 - (1-k) + (1+R)^2\right)}}{(1+R)k^2} \cdot V_t$$

$$\text{Let } \alpha_0 \equiv \frac{-\left[(1+R)^2 + k - (1+R)k^2\right] + \sqrt{\left[(1+R)^2 + k - (1+R)k^2\right]^2 + 2k^2(1+R)\left(-\frac{1}{2}(1+R)k^2 - (1-k) + (1+R)^2\right)}}{(1+R)k^2} \cdot V_t$$

Then α must satisfy the following:

$$-\frac{1}{2}(1+R)k^2 - (1-k) + (1+R)^2 = R^2 + 2R + k - \frac{1}{2}k^2$$
$$-\frac{1}{2}Rk^2 > 0, \text{ thus } \alpha_0 > 0.$$

A.2. Proof of Proposition 2

Proof

$$B - \alpha = \sqrt{(V_t - \alpha)W} - V_t + \alpha - \alpha = \sqrt{(V_t - \alpha)W} - V_t$$

$$(V_t - \alpha)W = (V_t - \alpha)\left\{\frac{1}{1+R}\frac{1}{2V_t}k^2(V_t - \alpha)^2 + \frac{\alpha + (1-k)(V_t - \alpha)}{(1+R)^2}\right\}$$

$$< (V_t - \alpha)\left[\frac{1}{2V_t}k^2(V_t - \alpha)^2 + \alpha + (1-k)(V_t - \alpha)\right]$$

$$= \frac{V_t - \alpha}{2V_t}\left[k^2(V_t - \alpha)^2 - 2V_t k(V_t - \alpha) + 2V_t^2\right]$$

$$= \frac{V_t - \alpha}{2V_t}\left[(k(V_t - \alpha) - V_t)^2 + V_t^2\right]$$

$$< \frac{V_t - \alpha}{2V} \cdot 2V_t^2 = (V_t - \alpha)V_t < V_t^2$$

That is, $\sqrt{(V_t - \alpha)W} < V_t$. Therefore, $B - \alpha < V_t - V_t = 0$.

A.3. Proof of Corollary 1

The arbitrageurs' payoff is:

$$\frac{WB}{V_t - \alpha + B} - B = \frac{W \cdot (\sqrt{(V_t - \alpha)W} - V_t + \alpha)}{\sqrt{(V_t - \alpha)W}}$$
$$- \sqrt{(V_t - \alpha)W} + (V_t - \alpha)$$

$$= W - 2\sqrt{(V_t - \alpha)W} + (V_t - \alpha)$$

$$= \left(\sqrt{V_t - \alpha} - \sqrt{W}\right)^2$$

A.4. Proof of Proposition 4

Proof If $\Omega \geq \Omega_0$, the minimum premium the target demands is zero. Given $\Omega \geq \Omega_1$, the premium that the acquirer is willing to pay is no less than zero. Therefore, the acquirer pays zero premium and the merger is feasible.
If $\Omega < \Omega_0$, the target demands a positive premium: $\alpha - V_t + \frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha kV_t}{C}(V_a + V_t - \alpha)$. The sufficient condition for the acquisition to be feasible is that the

maximum premium the acquirer is willing to pay is no less than the minimum premium demanded by the target, that is:

$$V_a - \frac{(V_a + \phi)V_t}{C}(V_a + V_t - \alpha) > \alpha - V_t$$
$$+ \frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha kV_t}{C}(V_a + V_t - \alpha)$$

It is equivalent to:

$$C - \frac{1}{2}k^2(V_t - \alpha)^2 - (1-k)V_t^2 - \alpha kV_t - (V_a + \phi)V_t > 0$$

$$C - \frac{1}{2}k^2(V_t - \alpha)^2 - (1-k)V_t^2 - \alpha kV_t - (V_a + \phi)V_t$$

$$(V_a + V_t)(V_t + \Omega) - k(V_a + V_t)(V_a + V_t - \alpha + \Omega)$$
$$= + k\alpha\Omega + \frac{1}{2}V_\alpha^2 + V_a V_t + \frac{1}{2}k^2(V_a + V_t - \alpha)^2 - \frac{1}{2}k^2(V_t - \alpha)^2$$
$$- (1-k)V_t^2 - \alpha kV_t - V_a V_t - \phi V_t$$

$$V_a V_t + V_a \Omega + \Omega V_t - kV_a^2 - 2kV_a V_t + \alpha kV_a$$
$$= -\Omega kV_a - \Omega kV_t + k\alpha\Omega + \frac{1}{2}V_\alpha^2 + \frac{1}{2}k^2V_a^2 + k^2V_a V_t$$
$$- \alpha k^2 V_a - \phi V_t$$

$$= \frac{1}{2}V_a^2(1-k)^2 + V_a V_t(1-k)^2 + \Omega V_a(1-k) + \alpha kV_a(1-k)$$
$$+ \Omega V_t(1-k) + \alpha \Omega k - \phi V_t$$

Therefore Equation 57.18 holds if and only if

$$\Omega[(1-k)(V_a + V_t) + \alpha k] + \frac{1}{2}V_\alpha^2(1-k)^2 + V_a V_t(1-k)^2$$
$$+ \alpha V_a k(1-k) - \phi V_t > 0$$

That is:

$$\Omega > -\frac{\frac{1}{2}V_\alpha^2(1-k)^2 + V_a V_t(1-k)^2 + \alpha V_a k(1-k) - \phi V_t}{(1-k)(V_a + V_t) + \alpha k}$$

$$(57.18)$$

A.5. Proof of Proposition 5

Proof

$$\rho_0 - \alpha = \max(\alpha - V_t + \frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha kV_t}{C}$$
$$(V_a + V_t - \alpha) - \alpha, -\alpha)$$

$$= \max\left(\frac{-CV_t + (\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha kV_t)(V_a + V_t - \alpha)}{C}, \alpha\right)$$

Since $C > 0$, $\frac{-CV_t + (\frac{1}{2}k^2(V_t-\alpha)^2 + (1-k)V_t^2 + \alpha kV_t)(V_a + V_t - \alpha)}{C} < 0$ is equivalent to:

$$-CV_t + \left(\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha kV_t\right)(V_a + V_t - \alpha) < 0$$

$$-CV_t + \left(\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha kV_t\right)(V_a + V_t - \alpha)$$

$$= -\frac{1}{2}\alpha V_t^2(1-k)^2 - \frac{1}{2}V_a^2 V_t(1-k)^2 - \frac{1}{2}V_a V_t^2(1-k)^2$$
$$- \alpha^2 kV_t(1-k)$$
$$- \frac{1}{2}(V_a V_t^2 - V_a \alpha^2 k^2 + \alpha^3 k^2 + \alpha V_t^2) - \Omega V_t(V_a + V_t)$$
$$(1-k) - \Omega V_t \alpha k$$

Thus, $\frac{-CV_t + (\frac{1}{2}k^2(V_t-\alpha)^2 + (1-k)V_t^2 + \alpha kV_t)(V_a + V_t - \alpha)}{C} < 0$ is equivalent to

$\Omega > \Omega_3$, where.

$$\Omega_3 = \frac{-(\frac{1}{2}\alpha V_t^2 + \frac{1}{2}V_a^2 V_t + \frac{1}{2}V_a V_t^2)(1-k)^2 - k\alpha^2 V_t(1-k) - \frac{1}{2}(V_a V_t^2 - V_a \alpha^2 k^2 + \alpha^3 k^2 + \alpha V_t^2)}{V_t((V_a + V_t)(1-k) + \alpha k)}$$

Because $\alpha < V_t$ and $k < 1$, Ω_3 is negative.

A.6. Proof of Corollary 2

Proof Both Ω_1 and Ω_0 are functions of α. For any given positive α, the merger is feasible if $\Omega \geq \Omega_1$ and $\Omega \geq \Omega_0$ from Proposition 4. That is, $\Omega \geq \max(\Omega_1, \Omega_0)$.

From Proposition 4, we know that if $\Omega < \Omega_0$, the merger is still feasible as long as $\Omega \geq \frac{-\frac{1}{2}V_a^2(1-k)^2 - V_a V_t(1-k)^2 - \alpha V_a k(1-k) + \phi V_t}{(1-k)(V_a + V_t) + \alpha k}$. This scenario implicitly specifies that $\Omega_1 \leq \Omega_0$. $\Omega_1 \leq \Omega_0$ is equivalent to:

$$\frac{(V_a + \phi)V_t}{V_a} < \frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha kV_t}{V_t - \alpha}$$

The above inequality is equivalent to:

$$\frac{1}{2}k^2 V_a \alpha^2 + [(V_a + \phi)V_t + kV_a V_t(1-k)]\alpha$$
$$+ V_a(-kV_t^2 + \frac{1}{2}k^2 V_t^2) - \phi V_t^2 \geq 0$$

Since $\alpha > 0$, the above inequality is equivalent to:

Appendix B: Deriving the Propositions Under the Case of $k \frac{V_a}{V_a + V_t - \alpha}$

If $k < \frac{V_a}{V_a + V_t - \alpha}$, $V_a + V_t - \alpha + \gamma$ will always be greater than $k(V_a + V_t - \alpha)$. In this case, the risk of early liquidation does not exist for the shareholders of the combined firm. The target shareholders' expected payoff, in a stock for stock exchange, from the acquisition, is then:

$$\frac{V_t - \alpha + \rho}{V_a + V_t - \alpha}(V_a + V_t + \Omega) \qquad (57.19)$$

The target's shareholders will accept the offer if

$$\frac{V_t - \alpha + \rho}{V_a + V_t - \alpha} \cdot (V_a + V_t + \Omega) \geq \frac{1}{2}k^2 \frac{(V_t - \alpha)^2}{V_t} + (1-k)V_t + \alpha k \qquad (57.20)$$

i.e., the premium ρ has to satisfy the following:

$$\rho \geq \alpha - V_t + \frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha kV_t}{V_t(V_a + V_t + \Omega)} \cdot (V_a + V_t - \alpha) \qquad (57.21)$$

The minimum premium demanded by the target decreases in Ω. That is, rational target would tradeoff merger premium and share of post merger expected gain in a stock for stock exchange; he higher the post merger gain is, the lower is the premium demanded by the target. We restrict the premium to be nonnegative, therefore the target demands the premium as, $\rho \geq \max(\alpha - V_t + \frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha kV_t}{V_t(V_a + V_t + \Omega)}(V_a + V_t - \alpha), 0)$. That is, (1) if $\alpha - V_t + \frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha kV_t}{V_t(V_a + V_t + \Omega)}(V_a + V_t - \alpha) \geq 0$, the target demands the premium $\rho \geq \alpha - V_t + \frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha kV_t}{V_t(V_a + V_t + \Omega)} \cdot (V_a + V_t - \alpha)$; (2) if $\alpha - V_t + \frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha kV_t}{V_t(V_a + V_t + \Omega)}(V_a + V_t - \alpha) < 0$, the target demand the premium of 0. $\alpha - V_t + \frac{\frac{1}{2}k^2(V_t - \alpha)^2 + (1-k)V_t^2 + \alpha kV_t}{V_t(V_a + V_t + \Omega)}(V_a + V_t - \alpha) \geq 0$ is equivalent to $\Omega \leq$

$$\alpha \geq \frac{-[(V_a + \varphi)V_t + kV_a V_t(1-k)] + \sqrt{[(V_a + \varphi)V_t + kV_a V_t(1-k)]^2 + 2k^2 V_a(kV_a V_t^2 - \frac{1}{2}k^2 V_a V_t^2 + \varphi V_t^2)}}{k^2 V_a}.$$

$\frac{(\frac{1}{2}k^2(V_t-\alpha)^2+(1-k)V_t^2+\alpha kV_t)(V_a+V_t-\alpha)}{V_t(V_t-\alpha)} - V_a - V_t$. Let us denote $\frac{(\frac{1}{2}k^2(V_t-\alpha)^2+(1-k)V_t^2+\alpha kV_t)(V_a+V_t-\alpha)}{V_t(V_t-\alpha)} - V_a - V_t$ as Ω_0.

The acquirer shareholder's expected value, in a stock for stock exchange, at date 2 is:

$$\frac{V_a-\rho}{V_a+V_t-\alpha}(V_a+V_t+\Omega) - \phi \qquad (57.22)$$

ϕ is the acquirer's merger cost excluding the premium, for example, investment banking fees. ϕ is a positive number.

The acquirer shareholder's expected value, without the acquisition, at date 2 is V_a. Therefore, the acquirer will make the arbitrage motivated acquisition if

$$\frac{V_a-\rho}{V_a+V_t-\alpha}(V_a+V_t+\Omega) - \phi \geq V_a \qquad (57.23)$$

That is, $\rho \leq V_a - \frac{(V_a+\phi)}{V_a+V_t+\Omega}(V_a+V_t-\alpha)$.

Because the premium is restricted to be nonnegative, the acquirer offers the following premium schedule:

If $V_a - \frac{(V_a+\phi)}{V_a+V_t+\Omega}(V_a+V_t-\alpha)>0$, then $\rho \in [0, V_a - \frac{(V_a+\phi)V_t}{C}(V_a+V_t-\alpha)]$;

If $V_a - \frac{(V_a+\phi)}{V_a+V_t+\Omega}(V_a+V_t-\alpha)=0$, then $\rho=0$.

Proposition 6 *The necessary condition for the merger to be feasible is that* $V_a - \frac{(V_a+\phi)}{V_a+V_t+\Omega}(V_a+V_t-\alpha) \geq 0$. *That is,*

$$\Omega \geq \frac{V_a+\phi}{V_a}(V_a+V_t-\alpha) - V_a - V_t. \qquad (57.24)$$

Proof If $V_a - \frac{(V_a+\phi)}{V_a+V_t+\Omega}(V_a+V_t-\alpha)<0$, then the premium the acquirer is willing to offer has to be below zero, which violates the nonnegative premium constraint. Thus the merger is not feasible in that case.

Let us denote $\frac{V_a+\phi}{V_a}(V_a+V_t-\alpha) - V_a - V_t$ as Ω_1. Ω_1 is a decreasing function of α. That is, the higher is the magnitude of undervaluation, the lower is the minimum value of post merger gain that is necessary for the acquirer to participate in the merger.

Proposition 7 *Given* $\Omega \geq \Omega_1$, *if* $\Omega \geq \Omega_0$, *the merger is feasible. Given* $\Omega \geq \Omega_1$, *if* $\Omega<\Omega_0$, *the merger is still feasible*

as long as $\Omega \geq \Omega_2 \equiv \frac{\frac{1}{2}k^2(V_t-\alpha)^2-kV_t^2+\alpha kV_t+\phi V_t}{V_t}$.

The proof is similar to that of Proposition 4.

Corollary 3 *For any magnitude of undervaluation,α, the merger is feasible as long as* $\Omega \geq \max(\Omega_1,\Omega_0)$; *when* $\alpha \geq \alpha_1$, *the merger is also feasible as long as* $\Omega \geq \frac{\frac{1}{2}k^2(V_t-\alpha)^2-kV_t^2+\alpha kV_t+\phi V_t}{V_t}$, *where*

$$\alpha_1 = \frac{-[(V_a+\varphi)V_t+kV_aV_t(1-k)] + \sqrt{[(V_a+\varphi)V_t+kV_aV_t(1-k)]^2 + 2k^2V_a(kV_aV_t^2-\frac{1}{2}k^2V_aV_t^2+\varphi V_t^2)}}{V_ak^2}.$$

The proof is similar to that of Corollary 2.

Abstract

This paper provides an extensive review of research on the equity premium puzzle, providing an overview of the existing approaches to this problem. We then propose an alternative approach including the application of the stable distribution. We analyze a portfolio optimization problem, under the assumption of normal (Gaussian) and stable (non-Gaussian) distributed asset returns. We examine and compare the results of portfolio allocations obtained in normal and stable cases. Finally, we investigate the ratio between the coefficients of risk aversion in normal and stable cases.

58.1 Introduction

The term "equity premium" refers to the return on Stocks in excess of the return to a short-term "risk-free" instrument such as U.S. Treasury Bills. Mehra and Prescott (1985) first coined the term "Equity Premium Puzzle." Their analysis, based on historical data for the 90-year period from 1889 to 1978, found that the equity premium exceeds estimates from standard asset pricing models by large magnitudes.

To provide insight as to the magnitude of the puzzle, note that real returns to U.S. government bonds average approximately 1% per year historically, while real returns to the U.S. equities average 7% per annum (Kocherlakota, 1996). In comparison, standard economic models suggest the equity premium should be much smaller, in the range of 2–3% per year. Thus, general utility-based theories of asset prices have difficulty explaining why the magnitude of the equity premium observed from historical data is so great.

The "equity premium puzzle" brings to light an important issue in financial economics and challenges market efficiency. To illustrate, consider that if the return to equity investments is too high, why don't investors allocate massive amounts of their wealth to stocks and reject low-returning bonds, thereby raising the price of stocks which will lower their subsequent returns? Thus, in equilibrium, the theoretical models do not accurately describe the actions of individuals collectively, suggesting that individuals base their decisions on different criteria.

To address the "puzzle," the economics literature has focused on modifications to the formal utility-based theory and refinements and expansions of data sources. Despite much work in this area, the puzzle remains unsolved in that the plausible models still fail to wholly and adequately resolve the disconnect between the historical equity premium and estimates produced by the models.

Attempts to resolve the puzzle have become one of the major motive research in Finance and Economics. A number of generalizations to key features of the Mehra and Prescott (1985) model have been proposed in order to bring the models inline with the data. The following list summarizes these generalizations:

- **Behavioral explanations** (see Barberis et al., 2001; Mehra and Sah, 2002).

Despite the numerous attempts at solving the equity premium puzzle, none of these attempts have fully resolved or explained the anomalies.

This chapter is organized as follows. Section 58.1 describes the initial model and assumptions set forth by Mehra and Prescott (1985). Sections 58.2 and 58.3 discuss numerous existing approaches to the equity premium puzzle, including the point of view that there is no equity premium puzzle at all. Section 58.4 describes the stable distribution, highlighting its advantages over the normal distribution in empirical data analysis. Sections 58.5 and 58.6 propose an alternative model, considering the stable distribution assumption.

58.1.1 The Lucas' Asset Pricing Model (CCAPM) and Standard Preferences

We begin with a description of the model set forth by Mehra and Prescott (1985). Their model is a variation of the pure exchange model of Lucas (1978). According to the model, there exists a maximization problem of an agent at date t, who has endowment each period, and decides whether to invest in some risky asset with price p_t and payoff x_{t+1}. The agent faces uncertainty concerning the date $t + 1$ payoff. Therefore, at time t, the agent faces their investment decision and bases that decision on their expectations, conditioned on all available information as of date t.

The formal description of the maximization problem is as follows:

$$\max_{\{\xi\}} u(c_t) + E_t \beta u(c_{t+1})$$
$$c_t = e_t - p_t \xi$$
$$c_{t+1} = e_{t+1} + x_{t+1}\xi,$$

where e is the original consumption level, assuming the agent did not invest in the asset, and ξ is the amount of wealth the agent invests in the asset. The first order necessary condition is:

$$p_t u'(c_t) = E_t[\beta u'(c_{t+1}) x_{t+1}],$$

or equivalently may be expressed as any of the following asset pricing equations:

$$p_t = E_t[m_{t+1} x_{t+1}]$$
$$1 = E_t[m_{t+1} R_{t+1}]$$
$$1 = E[mR],$$

where the risky return, R_{t+1}, is $R_{t+1} = \frac{x_{t+1}}{p_t}$, and m_{t+1} is the *stochastic discount factor*. The stochastic discount factor is frequently referred to as the *pricing kernel* or *intertemporal marginal rate of substitution* since $m_{t+1} = \beta \frac{u'(c_{t+1})}{u'(c_t)}$.

The investor's preferences concerning random consumption are ordered by the increasing concave utility function U, which is restricted to be of the constant relative risk aversion class in order to insure that the equilibrium return process is stationary. The individual's utility function is:

$$U(c) = \frac{c^{1-\gamma}}{1-\gamma},$$

where $c = c_{t+1}/c_t$ is the consumption growth, or one plus the growth rate, and γ is the coefficient of relative risk aversion, which influences greatly the risk premium. Mehra and Prescott (1985) assume that the growth rate of consumption and dividends are distributed log-normally.

The parameter γ measures the curvature of the utility function. When fitting the model to actual data, estimates of γ provide important information regarding how well the model represents the choice problem. Large estimated values of γ, those significantly exceeding 1, correspond to risk-seeking individuals and give rise to the question "why is the average equity return so high relative to the average risk-free rate." On the other hand, if γ is near zero, i.e. individuals are nearly risk-neutral, then the question becomes "why is the average equity return so high?"

Numerous studies calibrate the coefficient of risk aversion based on a series of questions designed to identify an

individual's risk preferences. Based on these studies, it becomes evident that the coefficient of risk aversion should be a small number, certainly less than 10. Even in the marginal case, however, if the risk aversion coefficient is 10 and the discount factor is 0.99, the risk-free rate equals 12.7% and return on equity is 14.1%. This means that the equity risk premium is 1.4%, which is significantly lower than the historically observed equity premium (6.18%). Most studies find the optimal value of the risk aversion coefficient to be close to 3. Under those parameters, the risk-free rate will be even higher and the corresponding risk premium lower. Based on this evidence, consideration of various, plausible degrees of risk aversion fail to resolve the equity premium puzzle.

Researchers have found that the Lucas asset pricing model fits the empirical data well, especially in the context of macroeconomic research on Real Business-Cycle Theory. The model easily replicates the essential macroeconomic features of the business cycle (see Kydland and Prescott, 1982). On the other hand, the model does not fit well the financial market data on stock returns, resulting in the equity premium puzzle.

Philippe Weil (1989) raises an additional puzzle, the **risk-free rate puzzle**. This puzzle pertains to the high risk-free rate generated by the high risk aversion coefficient value necessary for the model to produce a large equity premium. Under the assumption of log normally distributed growth rate of consumption and dividends, the risk-free rate may be decomposed into the following components:

$$\ln R_f = -\ln \beta + \alpha \mu_x - \frac{1}{2} \alpha^2 \sigma_x^2 + \varepsilon.$$

The first term, $-\ln \beta$, is a time preference or impatience term, i.e. $\beta < 1$ reflects the fact that agents prefer early consumption to later consumption. Therefore, the conditions of perfect certainty and no growth in consumption result in the unique interest rate in the economy: $R(f) = 1/\beta$.

The second term, $\alpha \mu_x$, results from consumption growth. For high levels of expected future consumption, agents borrow against future consumption, aiming to smooth their lifetime consumption. Greater curvature of the utility function results in larger consumption growth rates, thus increasing the desire to smooth consumption. In the equilibrium this results in a higher interest rate since the aggregate agents cannot simultaneously increase their current consumption.

The third term, $\frac{1}{2} \alpha^2 \sigma_x^2$, results from demand for risk-free saving. Facing uncertainty, agents seek to protect themselves against future unfavourable consumption levels by creating reserves of the consumption good. The result is that, in the equilibrium, the interest rate falls to as a result of the increasing demand for savings.

The fourth term, ε, is a risky term, describing the residual and the variance not explained by the model.

Hansen and Jagannathan (1991) provide an alternative perspective on the equity premium puzzle. They investigate the mean-variance frontier, which presents the maximum expected return for a given level of risk as measured by variance. All portfolios of risky assets lie inside the mean-variance frontier. The portfolios on the frontier present the optimal return-per-unit-risk and are correlated with each other and with the discount factor m.

The slope of the mean-standard deviation frontier $\sigma_t(m_{t+1})/E_t(m_{t+1})$ is the largest available ratio of mean excess return to standard deviation (Sharpe ratio):

$$\left| \frac{E_t(R_{t+1}) - R_t^f}{\sigma_t(R_{t+1})} \right| \leq \frac{\sigma_t(m_{t+1})}{E_t(m_{t+1})} \approx \gamma \sigma_t(\Delta c_{t+1})$$

where R_{t+1} is the risky return, $R_t^f = 1/E(m_{t+1})$ is risk-free return. This inequality reflects the equity premium puzzle and appears to be the Hansen-Jagannathan lower bound on the pricing kernel.

The slope of the mean-standard deviation frontier is larger if the economy is more risky, consumption is more volatile, or investors are more risk averse. The empirical post-war US data illustrate that the observed slope is much higher than suggested by reasonable risk aversion and consumption volatility estimates. With a Sharpe ratio of 0.5 and with $\gamma \sigma_t(\Delta c_{t+1}) = 0.01$, investors should have a risk aversion coefficient of $\gamma \approx 50$ or more, whereas various measures of risk aversion in the empirical data indicate a risk aversion below 10. According to this specification, the equity premium puzzle may result for the following reasons:

1. Investors are much more risk averse than expected;
2. Investors had good luck in the last 50 years, benefitting from a string of positive draws from the distribution of risky outcomes;
3. The model suffers from critical flaws.

Mehra and Prescott (1985), as mentioned above, use an extension of Lucas' (1978) asset-pricing model to estimate the premium for bearing systemic risk. Important to their analysis are the restrictions placed on the risk aversion parameter. Estimating the relative risk aversion parameter using statistical tools differs meaningfully from estimating the equity risk premium. Mehra and Prescott (1985) did not estimate the risk aversion parameter and did not estimate the discount rate parameters. Additionally, they reject extreme risk aversion based on observations on individual behaviour, which include the small size of premia for jobs with uncertain income and the limited amount of insurance against idiosyncratic income risk. Individuals with limited access to capital markets make investments in human capital resulting in very uneven consumption over time.

The basic growth model, when restricted to be consistent with the actual economic growth, generates business cycle fluctuations only if the risk aversion parameter is near zero.

This corresponds to the log case in standard usage. Importantly, the risk aversion parameter appears in various observations at both the household and the aggregate levels and appears to be small. Mehra and Prescott find that for all values of the risk-aversion coefficient less than 10, which is decided to be the upper limit value for this parameter, a premium for bearing aggregate risk is not related significantly to the historic equity premium.

58.1.2 Equity Premium Puzzle in Different Countries

Historically, stock returns have been considerably higher than the relatively risk-free security. This result obtains from the estimates of the equity premium based on the various data sets used in the literature and application of consumption-based asset pricing models (C-CAPM). The U.S. equity market is not unique in terms of the large historical equity premium. Large equity excess returns are also observed in countries with sizeable capital markets, such as UK, Japan, Germany and France. Mehra and Prescott (2003) illustrate the equity premium in the post-war period for these countries using data based on Campbell (2001).

The annual return on the British stock market was 5.7% over the period of 1947–1999, whereas the average equity premium of 4.6% exceeds significantly the average return of 1.1% on a relatively risk-free security. They find similar results for Japan, Germany and France: average returns on risk-free securities and average equity premia reached 1.4% and 3.3%, 3.2% and 6.6%, 2.7% and 6.3% respectively for these countries. Moreover, empirical investigation of the Japanese markets during the period of 1980–1997 (Naohiko Baba 2000) suggests that the risk-free rate puzzle is an even more compelling phenomenon than the equity premium puzzle in Japan during this period.

Engsted, Mammen, and Tanggaard (2001) investigate the Consumption CAPM (C-CAPM) and the equity premium puzzle using asset returns and consumption data from the US and Denmark. Their analysis finds large differences between US and Danish asset markets. Their results depend to some extent on the length of the investment horizon. It is worth noting that earlier work focuses attention on short investment horizons (1 year). Engsted et al. (2000) investigate the effect of altering the horizon. The main results show that the evidence against the C-CAPM becomes much weaker when the horizon is extended from 1 to 5 years. The results for the Danish data show that risk-adjusted equity premia are insignificant even with low values of the risk aversion coefficient. However, according to tests of the model, it cannot be claimed that there is no equity premium puzzle evident. Indeed, the equity premium has varied considerably over time and the variation depends mostly on the time horizon over which researchers measure the premium. During certain periods, the equity risk premium varied to enough to produce negative premia.

58.2 Approaches to the Equity Premium Puzzle

Studies of the equity premium puzzle typically consider three specific assumptions. Each of these assumptions has been challenged in the literature, as we will describe in subsequent sections. These are:

1. *Beliefs and preferences*. Research assumes the specified utility function reflects the preferences of every investor. Although all investors may act as if they have the same utility function, this does not imply that the *stochastic discount factor, m,* is the same for everyone. Multiple values of the stochastic discount factor, *m*, makes the theory difficult to apply. Therefore, a tractable solution requires one, unique *m*. In one approach, it is assumed that all investors are identical, i.e. there is a representative investor. This restrictive condition may be relaxed by instead assuming that markets are complete.

2. *Complete markets*. Markets are complete when there exists, for each state, an asset with a payoff of one unit of wealth if that state occurs and zero if any other state occurs. The assumption that markets are complete does not mean that there is no uncertainty, but instead may be interpreted that agents are able to insure against every risky outcome. Under this assumption, it is possible to demonstrate that the stochastic discount factor is the same for all investors.

3. *Frictionless markets*. Most research makes the assumption that there are no transactions costs or constraints on asset trades. This unrealistic assumption may be a reason for the failure of the model to explain the observed equity premium.

58.2.1 Time and State Preferences

State dependent preferences have a long history in economics. Epstein and Zin (1991) present a class of preferences they refer to as "Generalized Expected Utility" (GEU) which allow for independent parameterization of the coefficient of risk aversion and the elasticity of inter-temporal substitution. In this framework, asset prices result from both the covariance with the growth rate of consumption and with the return on the wealth portfolio. This captures the pricing features of both the standard consumption CAPM and the traditional static CAPM. Another feature of this class of models is that a high coefficient of risk aversion does not necessarily imply that agents want to smooth consumption over time.

However, difficulty arises when testing this alternative preference structure involving variables that are unobservable, making calibration difficult. Epstein and Zin (1991) use the "market portfolio" to measure the wealth portfolio and suppose that their framework offers a solution to the equity premium puzzle. However it was found that their choice of proxy for the wealth portfolio exaggerates the correlation between asset returns and the wealth portfolio.

The preferences suggested by Epstein and Zin separate the coefficient of relative risk aversion (CRRA) from the elasticity of intertemporal substitution. Melino and Yang (2003) generalize the model of Epstein and Zin by allowing the representative agent to display state dependent preferences. Various combinations of state dependent CRRA with state dependent elasticity of intertemporal substitution were investigated. Under the condition of constant elasticity of inter-temporal substitution and time varying CRRA, the results are very similar to those generated without state preferences.

Another approach combines a state dependent elasticity of intertemporal substitution with a state dependent coefficient of relative risk aversion. In this approach, the model produces results that match the U.S. historical record. The additional restriction imposed by this class of preferences is that the coefficient of risk aversion depends strictly on the elasticity of inter-temporal substitution. Under this assumption, an agent averse to consumption variation across different states *at a particular point of time* is then averse to *consumption variation over time*. Mehra and Prescott (2003) find that there is no reason why this condition must be true. Since consumption is growing over time on average, the agents in the Mehra and Prescott (1985) study have no particular need to save. This modification can potentially resolve the risk-free rate puzzle under the log-normality assumptions and using the market portfolio as a representative for the wealth portfolio. It cannot, however, resolve the entire equity premium puzzle.

58.2.2 Habit Formation

Constantinides (1990) presents a new approach which is referred to as "habit formation." According to habit formation, an agent's utility is affected both by current and past consumption levels. Thus, habit formation captures a fundamental feature of human behaviour: that individuals adjust to a certain level of consumption and prefer strongly to avoid subsequent decreases in their consumption level. Two types of habit can be defined and are referred to as "internal" and "external" while there are two modelling perspectives, referred to as "difference" and "ratio". Internal habit formation captures the notion that utility is a decreasing function of one's own past consumption and marginal utility is an increasing

function of one's own past consumption. Models with external habit emphasize that the operative benchmark is the individual's level of consumption relative to other agents in the economy. Constantinides (1990) suggests a model with internal habit where utility is defined over the difference between current consumption and lagged past consumption.

According to the model, preferences make the agent extremely averse to consumption risk even when the level of risk aversion is small. Even if changes in consumption are small, changes in marginal utility may be large. Thus, while this approach can resolve the equity premium puzzle only with extreme aversion to consumption risk, it can be applied to the risk-free rate puzzle, since the resulting aversion to consumption risk increases the demand for bonds, whereas the risk-free rate is reduced. Furthermore, if the growth rate of consumption is assumed to be i.i.d., an assumption of this model is that the risk-free rate varies considerably over time. Since the model of Constantinides (1990) does not have an i.i.d growth rate, the model suffers from this problem.

An alternate approach to circumvent this problem has been proposed by Campbell and Cochrane (1999). Their model addresses the possibility of a decreasing state variable so that risk aversion varies in a highly nonlinear manner. Under reasonable parameter values, their model is able to generate a high equity premium, since the risk aversion of investors rises greatly when the chances of price declines become larger. Since risk aversion increases precisely when consumption is low, it generates a demand for bonds that results in lower risk-free rates. This model performs well when fit to both historical consumption and asset market data.

Abel (1990) presents another modification of the Constantinides (1990). Abel models a phenomena referred to as "keeping up with the Joneses". The intention is to define utility of consumption relative to average per capita consumption. Thus, the model is an external habit model where preferences are defined over the ratio of consumption to lagged aggregate consumption.

The idea is that one's utility depends not on the absolute level of consumption, but on one's consumption level relative to others'. The implication is that an individual can become extremely sensitive and averse to consumption variation. Since equity may have a negative rate of return, the agent faces risk of decreasing personal consumption relative to others. Therefore, equity becomes an undesirable asset compared to bonds.

Abel (1990) defines utility as the ratio of consumption relative to average per capita consumption rather than the difference between the two. This is not a trivial modification (Campbell, 2001) to preferences. While "difference" habit models can, in principle, generate a high equity premium, ratio models generate a premium that is similar to that obtained with standard preferences.

Otrok, Ravikumar and Whiteman (1998, 2001) present another model with habit preferences. They explore whether the introduction of habit preferences into the simple intertemporal consumption-based capital asset pricing model resolves the equity premium and risk-free rate puzzles. Otrok, Ravikumar and Whiteman demonstrate that agents with habit preferences care not only about overall volatility, but also about the temporal distribution of that volatility. Specifically according to the model, habit agents are much more averse to high-frequency fluctuations than to low-frequency fluctuations. The size of the equity premium in the habit model is intended to be determined by a relatively insignificant amount of high-frequency volatility in U. S. consumption. Furthermore, the model's premium and returns are highly sensitive to changes in characteristics of the stochastic process for consumption. Unfortunately, the model also carries counterfactual implications for the equally dramatic changes in the equity premium and risk-free rate observed over the last 100 years.

As compared with the previous approaches, Otrok, Ravikumar and Whiteman employe spectral utility functions to examine an agent's attitude toward the temporal distribution of consumption volatility. When the agent's preferences show intertemporal non-separabilities (e.g. habits), the asset pricing model has important implications for the equity premium and the risk-free rate of return. To isolate the solving method, spectral utility is applied to the equity premium puzzle in the habit model. The habit model produces the equity premium by showing extraordinary sensitivity to high-frequency fluctuations. Due to this sensitivity, as the volatility and serial correlation properties of U.S. consumption have changed during the last 100 years, the model makes counterfactual predictions of the time path of the equity premium and the risk-free rate. Therefore, important questions persist as to whether habit formation models can resolve the equity premium puzzle.

58.2.3 Idiosyncratic and Uninsurable Risk

Constantinides and Duffie (1996) develop a model with heterogeneous consumers to reflect the notion that consumers are dependent on idiosyncratic against which they are unable to insure themselves fully. Their model considers the consumers unable to insure against the risk of job loss or other major personal disasters. Equities and related investments possess the undesirable feature that they drop in price when the probability of job loss increases. In these situations, consumers require an extra incentive to hold equities and similar investment instruments. The equity premium results as the necessary enticement for these investors to hold risky equities. The model generates a high risk premium, but may not generate the required degree of consumption variation generated in an economy with agents who have a relatively low level of risk aversion.

Lettau (2001) evaluates models with idiosyncratic consumption risk using Hansen and Jagannathan's (1991) volatility bounds. Idiosyncratic risk helps to enter the bounds when this risk depends on the aggregate state of the economy. The model, however, does not pass the Hansen and Jagannathan test even for very volatile idiosyncratic income data. Therefore, Lettau's results suggest that the models with idiosyncratic uncertainty do not solve completely the equity premium puzzle.

58.2.4 Disaster State and Survival Bias

Rietz (1988) proposed a new approach to the equity premium puzzle. This approach considers scenarios having a very small probability of a very large drop in consumption. Rietz finds that in such a scenario the risk-free rate is much lower than the return on equity. To produce this result, the model requires a 1% probability of a 25% decrease in consumption and a risk aversion parameter of 10. Such a scenario has not been observed in the USA for the recent years during which economic data exist. However, such a scenario is unlikely to be observed so frequently that this approach could be put into practice.

Another attempt at resolving the puzzle comes from Brown et al. (1995) and focuses on survival bias. It is particularly important that measured returns reflect accurately the true premium earned by stock market investors. Many stock exchanges were unsuccessful, resulting in low expected equity premia. Since it was not known in advance which exchanges would survive, stock and bond markets must be differentially influenced by a financial crisis. Mehra and Prescott (2003) find that although a survival bias may influence the levels of both the return on equity and debt, there is no evidence to support the assumption concerning the differential influence on the returns to stocks and bonds. Therefore, the disaster state and survival model is not a solution to the equity premium puzzle.

58.2.5 Borrowing Constraints

Constantinides, Donaldson, and Mehra, (1998) present a new perspective on the equity premium puzzle with an overlapping-generations (OLG) economy in which a representative agent's life is divided into three overlapping periods. During the first period, the agent receives a

relatively low endowment income. During the second period the agent is employed and is exposed to large wage income uncertainty. Finally, during the third period the agent retires and consumes the assets accumulated in the second period. This approach is an attempt to address such questions as: (1) why is the historical equity premium so high; (2) why the real rate of interest is so low; and (3) why so few consumers hold equities and bonds.

The researchers consider two versions of the overlapping generations economy:
1. Borrowing-constrained version.
2. Borrowing-unconstrained version.

In the case where the agent faces borrowing-constraints, the equity premium exhibits low correlation with young workers' expected wage income during their middle ages. This is in contrast to the borrowing-unconstrained economy where the young agent borrows and invests in equities, leading to reduction of the mean equity premium while the interest rate rises. Therefore, the borrowing-unconstrained models suffer from difficulty explaining the high mean equity premium and the low rate of interest.

In the overlapping generations model, a natural question is "who invests in bonds if equity is so attractive to the young wage earners?" Since the savings oriented middle-aged experience uncertainty in their future wage income and the majority of their future income derives from their current savings in equity and bonds, they therefore prefer to hold a diversified portfolio that includes positive holdings of bonds, thus explaining the demand for bonds. The main features captured by the overlapping generation economy are that the future income of the young agents obtains from their wages during middle age, while the future income of the middle-aged agents derives from their savings through holdings of equities and bonds. As a result of this difference, the young have a distinct attitude to the mean equity premium compared the middle-aged.

As compared with equilibrium models, the OLG models have some important advantages. Equilibrium models that allow for consumer bond holdings, consistent with infinitely-lived consumers considered in some models, are difficult to construct. By contrast, in the OLG model the borrowing constraint plays a very different role in the consumers' life-cycle demand for equity and bonds.

The main contribution of the Constantinides, Donaldson, and Mehra, (1998) paper is that the borrowing-constraint results in a lower interest rate and larger equity premium. On the other hand, in the case with incomplete markets, none of the traded securities correspond to bonds and the equity premium cannot be computed. Furthermore, the model does not resolve the equity premium puzzle since increasing the equity and bond return results in a lower equity premium. Absent borrowing constraints, the demand for bonds reduces and the risk-free rate puzzle again presents.

58.2.6 Transaction Costs

An important assumption in the traditional model is that the agent may rebalance their portfolio, without cost, as many times as desired over their investment horizon. The presence of transaction costs implies that investors may reduce the frequency at which they transact, for example they may choose to rebalance only once every several years.

The combination of infrequent portfolio trades and high returns on equities over long periods makes it plausible that, for longer horizon, the larger are investors' portfolio allocations to equities. However, although equities offer high expected returns over long periods, they also bear the possibility of large losses. Thus, the agent's decision depends on their preferences towards risk. More risk averse investors likely hold smaller shares of equities regardless of the frequency at which they rebalance their portfolio holdings. The transaction costs approach does not resolve entirely the equity premium puzzle. At best, the transactions cost approach explains a few, select aspects of the puzzle.

58.2.7 Taxes

McGrattan and Prescott (2001) propose an explanation for the equity premium based on changes in tax rates. It is important that tax rate explanation is not risk-based so that an equity premium can be taken into account but not as an equity *risk* premium. McGrattan and Prescott find that, at least in the post-WorldWarII period, the equity premium is not puzzling after taking into account tax rates. They find that the significant decline in individual income tax rates and the increased opportunity to shelter income from taxation resulted in a doubling of equity prices between 1960 and 2000 and, therefore, the high observed returns on equity as compared to returns on debt. This argument can be illustrated by use of a simple one-sector model that includes only taxes on corporate distributions and taxes on corporate profits. Every agent seeks to maximize utility subject to their budget constraint, which represents the condition that the present discounted value of charges must be less than or equal to the discounted value of after-tax income. Agents' bear costs for their consumption and transactions of stocks. Agents receive income from three sources – dividends, wages, and government transfers. Agents pay personal taxes on dividend and wage income. The result of the study by McGrattan and Prescott (2001) is that a large increase in the personal tax rate with little change in the corporate tax rate raises indeed the value of equity. However, to show this interdependence, some specific conditions should be observed which are transitive.

Mehra and Prescott (2003) find another potential problem with investigating the McGrattan and Prescott model, which

arises because of the difficulty in identifying the marginal investor. The marginal tax rate and the rate that applies to the marginal investor may differ greatly, while the rate that applies to the marginal investor is relevant for asset pricing. McGrattan and Prescott obtained the estimate of this tax rate from the weighted average rate calculation, the reliability of which is, however, questionable.

58.2.8 Incomplete Markets

Researchers have long recognized that incomplete market structures are a potential explanation of the equity premium puzzle. The analysis of incomplete market structures has been conducted using different empirical methodologies, such as simulation techniques. Whereas some early investigations note that incomplete markets cannot solve asset pricing puzzles, it is now widely accepted that the presence of uninsurable risk in a model economy results in model estimates that more closely resemble the predicted asset returns observed in practice. The results from models where markets are not assumed to be complete are sensitive to a number of parameters that have to be measured before setting up the model to explain asset returns.

Jacobs (1999) presents one interpretation of the equity premium puzzle and the risk-free rate puzzle by focusing on the importance of incomplete market structures and on the measurement of the pricing kernel. Early papers on incomplete markets place large emphasis on asset pricing puzzles and less on statistical tests of the model. These tests are of great interest for asset pricing as their interpretation is sometimes problematic due to data limitations and the testing technique.

Jacobs (1999) investigates a different approach to the measurement error problem . It is important to consider the measurement error because it helps to lower the level of risk aversion. Jacobs' approach to analysing market incompleteness focuses on the restrictions implied by the model under a weaker set of assumptions, such as the following intertemporal Euler equations

$$1 = \beta E_t \left(\frac{c_{i,t+1}}{c_{i,t}} \right)^{\gamma-1} R_{rl,t+1}$$

$$1 = \beta E_t \left(\frac{c_{i,t+1}}{c_{i-t}} \right)^{\gamma-1} R_{ri,t+1}$$

where $c_{i,t}$ is the consumption of agent i in period t, $R_{rl,t+1}$ and $R_{ri,t+1}$ are the risk-free and the risky return between periods t and $t + 1$, β is the discount factor, E_t is the mathematical expectation conditional on information available at t, and 1-γ is the rate of relative risk aversion.

In the case where markets are incomplete, there are a maximum of T observations on N households. The solution to the optimization problem for these household data results

from a generalized method of moments (GMM) framework. To construct the statistic for the test, assume that the Euler equation errors for a household are uncorrelated over time. The correlation between different households at the same time is determined by the size of the "aggregate shock" influencing the economy at that time, and therefore may be nonzero.

The paper demonstrates that the incomplete markets setting may plausibly lead to resolution of a number of important issues in asset pricing, such as the equity premium puzzle and the risk-free rate puzzle. One of the potential problems with tests of incomplete markets, however, is the presence of substantial measurement error. While the rate of risk aversion implied by the Euler equations is affected, indication that measurement error is important, the level of risk aversion is still intuitively plausible for asset-holders. These conclusions support a number of notes in the existing literature on incomplete markets that are typically obtained using simulation techniques. The conclusion of this analysis is that inclusion of uninsurable risk can adjust better the predicted asset returns to those found in the historical record, but often results in new problems tied to other parameters.

58.3 Is There the Equity Premium Puzzle?

58.3.1 Adjusted Set of Measurements

McGrattan and Prescott (2003) argue in favour of revisions to the approach set forth by Mehra and Prescott (1985). In particular, they make the following suggestions:

1. The T-Bill rate should not be used as the 'risk-free' rate since most households hold long-term debt in their portfolios instead of short-term government paper;
2. The costs of holding diversified equity portfolios should be taken into account;
3. Taxes on dividends should be calculated on the base of the equity portfolio returns;
4. It should be considered that the equilibrium asset pricing condition, used by Mehra and Prescott (1985), did not hold during WWII and the Korean War as the government imposed restrictions on production, consumer credit, and financial market fluctuations.

Using long-term high-grade bonds (and municipal bonds) as the 'risk-free' instrument, and making adjustments (2) and (3) to equity returns (and abstracting from the regulated sub-period 1935–1960) results in average excess real returns less than 1%. In other words, the 'average equity premium puzzle' is no longer a puzzle under these modifications.

İmrohoroğlu (2003) use the measurements proposed by McGrattan and Prescott (2003) and examine various aspects of the equity premium puzzle in detail, including the related low risk-free rate and excess volatility puzzles. The result of the research are support for two of the statements by

McGrattan and Prescott (2003). Their adjustments do in fact solve the "average equity premium puzzle" and come close to solving the "risk-free rate puzzle". However, the low risk-free rate puzzle, and the excess volatility puzzle persist. Standard theory cannot take account for the excess volatility of equity returns relative to consumption growth and the low correlation of excess returns with aggregate consumption growth. An alternative point of view held by a group of academicians and professionals is that currently there is no equity premium and, by implication, no equity premium puzzle.

58.3.2 Statistical Data Analysis

One of the main discusion points in the equity premium puzzle literature is the reliability of the data sources for the early studies conducted on this topic. Mehra and Prescott (1985) subdivide the U.S. historical equity premium data into three sub-periods. Duringt he first subperiod, spanning the years 1802–1871, the equity return data are not particularly reliable for multiple reasons. First, the data are constructed of different market indexes and portfolios. Second, different numbers of stocks were used for the construction of the indexes during the different periods. Further, the structure of the indexes is not equivalent. Third, important details were not considered during index construction, such as the average of the bid and ask prices were used, ignoring transaction costs, and dividends were omitted from returns computations (Schwert, 1990; Macaulay, 1938).

During the second subperiod, which covers the years 1871–1926, the equity return data are also constructed from multiple sources, including newspapers and industrial portfolios. Unlike the indexes for the earlier sample period which ending in 1871, the return computations account for dividend distributions, so that these data better reflect true returns, although they are not themselves completely reliable. During this time period, there was no definitive source for the risk-free rate. Thus, Mehra and Prescott (1985) make critical assumptions regarding the index construction.

The equity return data during the third subperiod, beginning in 1926 are of the highest quality, owing to the fact that the NYSE and the Centre for Research in Security Prices databases provide more accurate financial data. Clearly there exist differences in data quality across each period, which suggests caution when interpreting results comparing results between the different time periods.

58.3.3 Merton's Model: Conflict with the Equity Premium Puzzle

Bossaerts (1995) emphasizes several facts that contradict the results of the seminal paper by Mehra and Prescott (1985). According to the results of Mehra and Prescott, they substitute the smooth per capita consumption on non-durables and services for the more variable true payment process when calculating the price of the market index. In fact, their theoretical equity premium constitutes a lower boundary for the actual premium. Hence, unlike the Mehra and Prescott (1985) conclusions, they do not reject Lucas's equilibrium model.

Mehra and Prescott (1985) compare the average risk premium (the difference between the average return on the market and the risk free rate) observed during the period from 1889 to 1978 against the calculated values using a general equilibrium model. Merton (1980), interested in estimating the expected return on the market, used an equilibrium model similar to the one used in Mehra and Prescott (1985). Both models are based on a Markov-type economy with a representative investor (agent) having a constant relative risk aversion utility function. Merton's model relates the equity premium to the variance of the market return:

$$R^e - R^f = \alpha \sigma^2$$

where R^e is the expected return on the market, R^f is the risk free rate, σ^2 is the variance of the market return and α is the investor's relative risk aversion. From Merton's investigation of monthly returns of the New York Stock exchange Index over the period of July, 1926–June, 1978, one can calculate a relative risk aversion equal to 1.89 (see Merton, 1980). The equity premium Merton observed over this 52 year period is close to the one in Mehra and Prescott's article. However, Mehra and Prescott's model implied a reasonable premium value, if one allows the relative risk aversion to be as high as 10. Mehra and Prescott's results clearly reject the equity premium model, whereas Merton's findings, in contrast, support the model.

Bossaerts (1995) finds that there was another mismatching of Mehra and Prescott's calculations. They state, that the sensitivity to δ, the standard deviation of the consumption growth rate, is larger. The average equity premium was roughly proportional to δ squared. To the contrary, Bossaerts argues that this runs contrary to the Modigliani-Miller dividend irrelevance theorem which states that the price of a security does not depend on the payout policy chosen by the firm. Mehra and Prescott generate this variance sensitivity by assuming that consumption equals output and dividends for all times t. Merton's model implies the same variance sensitivity: the equity premium is proportional to the variance of the market return. Therefore, Mehra and Prescott find the average equity premium over the period 1889–1978 to be much higher than the one implied by their model and the per capita consumption on non-durables and services over that period. Their test investigates the lower boundary on the equity premium. Using Mehra and Prescott's model, but restricting δ to equal the standard deviation of the market return, and

remembering that the equity premium is roughly proportional to δ squared, it follows that the equity premium should at most be well above the observed level. This is the corresponding upper boundary test. Hence, one can conclude that the average risk premium for the period 1887–1978 lies somewhere between a lower boundary and an upper boundary. It does not contradict either boundary implied by the Arrow Debreu general equilibrium model. To get a specific value for the required equity premium, Merton's method can be used. And his results for the period 1929–1978 indicate that the average equity premium is not inconsistent with the equilibrium model.

58.3.4 Rational Beliefs

Kurz and Beltratti (1996) determine that the equity premium puzzle is no puzzle at all by suggesting an approach utilizing the theory of rational beliefs equilibrium (RBE). In an RBE, agents require compensation for the uncertainty which is not permitted under rational expectations as in Mehra and Prescott (1985). The main idea of the approach is replacing of the theory of rational expectations with the theory of rational beliefs of which rational expectations as a special case. A number of tests of the rational expectations theory were presented by Kurz and Beltratti with a conclusion that this theory failed the tests permanently. As a conclusion, the theory of rational beliefs was applied to provide an intuitively simple explanation for the data which led to the equity premium puzzle.

The theory of RBE proposes that agents do not have "structural knowledge" about the economy, i.e. they do not know the correspondence between exogenous variables and asset prices or the true probability distribution of the dividend process. The component of prices attributing to the beliefs of the agents is *endogenous uncertainty*. It is the price uncertainty which the agents face in the market.

The equity premium calculations of Mehra and Prescott (1985) assume that only capital gains and losses which can be attributed to the variability of the exogenous variables factor into the risk faced by the agents. The implication of this assumption is that the Mehra and Prescott equity premium is calculated under the assumption of rational expectations of the agents, therefore excluding all the endogenous uncertainty. Kurz and Beltratti (1996) insist that the endogenous uncertainty is the dominant form of uncertainty in the equities markets.

58.3.5 The Equity Premium Puzzle, Looking Forward

In response to resent research's challenges to the existence of the equity premium puzzle, Mehra and Prescott (2003)

stress the distinction between different interpretations of the term "equity premium." The first is the *ex post*, or realized, equity premium which is the actual, historically observed difference between the return on the market as reflected by a stock index, and the risk-free rate, provided by the return on government bills. This definition of the equity premium corresponds to the premium puzzle addressed by Mehra and Prescott (1985). The second, related concept is the *ex ante* equity premium, a measure of the predicted premium, i. e. the equity premium that is *expected* to prevail in the future, or the conditional equity premium.

The choice of one of these interpretations of the equity premium is important for an investment advisor and depends on the planning horizon. The equity premium documented by Mehra and Prescott (1985) reflects very long investment horizons. The *ex post* equity premium is not useful as a forecast of the premium for the next few years, since it is the realization of a stochastic process over a defined period of time, and has varied considerably over time.

Furthermore, the variation in the realized premium depends on the time horizon over which it is measured.

Investors planning over short-term investment horizons wish to project the conditional, expected equity premium over that planning horizon. Even if the current equity premium is small, this does not imply that the historical premium was too high or that the equity premium has declined. Mehra and Prescott emphasize that researchers should not dismiss the equity premium puzzle, and emphasize the need to first understand the observed phenomena, and then obtain a plausible explanation why the future is likely to differ from the past and why one may not expect the equity premium puzzle to persist in the future. Absent such an explanation, Mehra and Prescott (2003) suggest that, on the basis of our current collective knowledge, that over the long term the equity premium is likely to be repeated in the same way that it has been in the past. The failure of financial and economic modelling to capture the characteristic that appears to make stocks relatively risky puts the vital capacity of using this class of models in question.

58.4 Stable Distributions

Investors base their financial investment decisions almost exclusively on the expected returns and risk associated with the initial investment possibilities. The distributive character of the returns is of great importance for the theoretical and empirical analysis in economics and finance. For instance, the portfolio and the option pricing theory are based on assumptions regarding distribution functions. Previous researchers have advocated the application of the stable distributions in portfolio optimization. Early theories proposed by Bachelier (see Clark, 1973) considered normal distribution assumptions. Other researchers, however, doubt

in the suitability of the normal distribution (see Mandelbrot, 1963a, b; Mandelbrot and Taylor 1967; Fama, 1965). In their research they find additional kurtosis, i.e. high peaks of the density function, which reject the normal distribution assumption. As an alternative, they suggested the stable distribution. Further research has confirms this assumption (see, among others, Teichmoeller, 1971; Officer, 1972; Mittnik et al., 1997). Balke and Fomby (1994) demonstrate that most of the economic time series exhibit non-Gaussian behaviour. Their analysis of 50 U.S. macro-economical series, includes the Consumer Price Index (the measure of price inflation), industrial nominal compensation per hour (measure of wage growth), yields on AAA bonds, S&P 500 stock price index and GNP deflated. According to their investigation, the residuals of the autoregressive models point at the obvious presence of excess kurtosis and skewness. The conclude that even after extending the analysis to include GARCH class models, excess kurtosis and/or skewness remain.

Ziemba (1974) uses the symmetric stable distribution in an approximating problem of portfolio optimisation. Unfortunately theoretical and computational difficulties have decreased the interest to this approach. However, theoretical research and the development of computer algorithms in recent years have stimulated the intensive use of the stable distributions. Recent research by Ortobelli, Huber, Rachev and Schwartz (2002), Ortobelli, Huber and Schwartz (2003), and Ortobelli, Rachev, Huber and Biglova (2003) compare the optimal distributions of risky and risk-free assets under alternative hypotheses of normal and stable distributed asset returns. In both one- and multi-period analysis, the results highlight that the assumed distributions result in up to 85% differences.

Monographies by Samorodnitsky and Taqqu (1994), and Janicki and Weron (1994) provide detailed descriptions of stable distributions properties along with numerical methods and computer simulations of generated random stable distributed variables and processes. We summarize briefly the characteristic of the stable distributions.

Compared to the normal distribution, stable distributions possess such features as heavy tails and high peaks of the density function relatively to the center and asymmetry is possible.

A stable distribution is characterized by the following parameters:
- α – index of stability or, characteristic parameter;
- β – skewness parameter of the density function;
- σ – scale parameter;
- μ – location parameter.

The parameter α is controls the behaviour of the distribution tails. Stable distributions act the same way under infinity as the Paretian distributions. In these terms, the tails of stable distributions correspond to the Paretian

type. The skewness (asymmetry) parameter, $\beta \in [-1, 1]$, reflects the extent of distributional asymmetry. If $\beta = 0$, then the distribution's density function is symmetric. If $\beta > 0$, the density function is skewed to the left, and the extent of skewness increases while β value comes closer to 1. The case when $\beta < 0$ corresponds skewness to the right. Parameter σ is scale parameter. In case of normal distribution $(\alpha = 2)$ $DX = 2\sigma^2$. Note here that dispersion is $2\sigma^2$, instead of σ^2, as compared with standard considerations. If $\alpha < 2$, dispersion DX does not exist. Parameter μ is location parameter, since in case of $\alpha > 1$ mathematical expectation E|X| $< \infty$ and $\mu = EX$. Generally, this interpretation is lacking, since EX can be not determined.

Summarizing the section, it is worth noting that stable distributions possess two attractive features:
1. Stable distributions have a domain of attraction; thus in this area the distributions of the observed values are also stable, or, rather they are close to the stable distribution features. Therefore, the "idealized" stable distribution does not distort the empirical distribution.
2. Each stable distribution has an index of stability, which does not depend on the observed time horizon. Index of stability can be considered as a general parameter, which can be applied for inference.

Stable distributions and stable processes are of significant importance as natural and likely candidates within construction of probability models of distributions and the evolution of financial indexes (e.g. currency rates, asset prices etc.). Although the application of the stable distributions in portfolio optimisation is not a new idea, theoretical and computational difficulties coupled with the theoretical failure in adjusting the empirical data to the models have hindered the advancement of this approach. Hence, theoretical research and computer technique development in recent years have stimulated the intensive use of the stable distributions.

58.5   Risk Measure

Value-at-Risk (VaR) is a widely used risk measure in applied finance (see Duffie and Pan, 1997), answering the question "what is the maximum loss corresponding to a specified confidence level?" There exist various methodologies for the modelling of VaR. For an ordered confidence level α of $(0;1)$ and time horizon Δt the measure of risk VaR estimates the maximum loss in the time period Δt with the confidence level α. If $f(R^p)$ is the distribution of the return losses for the final portfolio return, then 99% VaR is defined as 1% of the lower quantile of the return distribution. If the investor searches a compromise between average final return and 99% VaR of the final return, the criterion function can be defined as:

$$U(R^p) = E(R^p) - cVaR_{99\%}(R^p). \qquad (58.1)$$

See Huisman et al. (1999), and Basak and Shapiro (2001) for further details.

Although VaR is a very popular measure of risk, it has undesirable properties such as lack of sub-additivity (i.e. the risk of a portfolio with two instruments can be greater than the sum of individual risks of these instruments), non-convexity and non-smoothness Artzner et al. (1999) suggest an alternative measure of risk with more attractive properties named Conditional Value-at-Risk (CVaR), which is defined in the following way:

$$CVaR_{99\%} = E[R^p | R^p < VaR_{99\%}(R^p)]. \qquad (58.2)$$

CVaR may be optimised using linear programming and non-smooth optimisation algorithms, which allows for implementation across portfolios with very large numbers of instruments and scenarios. Numerical experiments indicate that the minimization of CVaR also leads to VaR optimisation, since CVaR is always greater than or equal to VaR.

58.6   The Model

The analysis considers a portfolio consisting of two types of assets: a risky asset and a relatively risk-free asset, such as Treasury Bill.

The investor aims to optimise their portfolio allocation to achieve the maximum utility. At the same time, it is necessary to invest all the money he has in the available assets. The share (weight) of each asset in the portfolio should be non-zero.

In the present work this problem is solved in a discrete statement, i.e. when there is a final set of admissible portfolios among which the investor makes their choice. The solution in this case results from an exhaustive search of all feasible portfolios in each definite case.

Apart from the problem of utility function maximization, there is the problem of the optimal risk aversion coefficient which describes the investor's attitude to risk. A large value of the coefficient means the investor exhibits high aversion to risk, requiring large expected returns to entice them to take additional units of risk.

The analysis assumes normal and stable asset returns distributions. The aim of this research is to define for which type of asset returns distribution (normal or stable), the decision on asset allocation approximates more closely the empirical data.

The aim of the investigation is to demonstrate the generalized results of the distributional assumptions.

Let us indicate the following parameters:

p – number of the portfolio, $p = 1,\ldots,100$;
$z_{i,t}$ – price of the asset i at moment t;
$r_{i,t}$ – return of the asset i at moment t;
$x_{i,p}$ – simulated weight of the asset i in portfolio p;
Rp – return of portfolio p;
$E(Rp)$ – mathematical expectation of portfolio return;
$CVaR_\varepsilon(Rp)$ – measure of portfolio risk under the error level ε;
ε – error level, $(1-\varepsilon)$ – confidence level;
c – coefficient of relative risk aversion;
$U(Rp)$ – portfolio utility function.

Formally, the problem can be represented in the following way:

$$\max U(Rp_t) = E[Rp_t] - c \cdot CVaR_\varepsilon(Rp_t), \qquad (58.3)$$

where the mathematical expectation of the portfolio return at moment t is calculated as follows:

$$E[Rp_t] = \frac{1}{N} \sum_{n=1}^{N} Rp_{n,t}. \qquad (58.4)$$

Portfolio return is defined as

$$Rp_t = \sum_{i=1}^{d} x_{i,t} \cdot r_{i,t}, \qquad (58.5)$$

where d is the number of the assets in the portfolio.

Portfolio risk or, the portfolio loss level is defined by the measure of risk $CVaR_\varepsilon(Rp)$ [52].

The admissible values of the coefficient of relative risk aversion are $c > 0$.

Since the values of $E[Rp_t]$ and $CVaR_\varepsilon(Rp_t)$ do not depend on the coefficient of relative risk aversion, the utility function of every portfolio as a function of risk aversion coefficient is linear:

$$U(c) = k \cdot c + b, \qquad (58.6)$$

where $U(c) = U(Rp_t)$; $b = E[Rp_t]$; $k = -CVaR_\varepsilon(Rp_t)k$, i.e. the plot of the utility function as a function of the risk aversion coefficient is represented as a straight line. Therefore, the plot of the optimal (maximum) utility function is the upper boundary of a set of these lines, i.e. is formed by the sections of these lines, where the corresponding line is the highest.

58.7   Calculations and Results Analysis

The analysis considers the following portoflios:
1. DowJonesIndustrials index and 3-month T-bill for the period of January 02, 1997–June 30, 2003 (1,563 days);

2. 24 assets included to the DAX30 index for the period of January 02, 1998–June 30, 2003 (1,387 days);
3. DAX30 index and 6-month EURIBOR for the period December 28, 1998–June 30, 2003 (1,139 days);
4. DAX30 and CAC40 indexes and 6-month EURIBOR for the period December 28, 1998–June 30, 2003 (1,146 days).

A historical vector of portfolio weights for October 10, 2004 was accepted as an empirical portfolio in the second case (the source of the data was Deutsche Börse AG).

For the cases 1 and 3, the standard vector of weights for portfolios including one risky and one risk-free asset was accepted as an empirical portfolio: 0.4 for risk free assets and 0.6 for risky assets. In case 4 the empirical optimal portfolio was defined in the following way: 0.4 is the weight of risk-free asset (Euribor), the rest 0.6 points for the risky assets were divided as 0.36 for CAC40 and 0.24 for DAX30, since it is empirically decided to consider the French assets 1.5 times more reliable than the German assets.

The plots of the density functions' histograms for simulated and empirical asset returns demonstrate that:

- The density functions of the empirical asset returns exhibit heavy tails, while the simulated normal asset returns do not. At the same time, the simulated stable asset returns are closer to the empirical data in the sense that the density function in the stable case also has heavy tails.
- The peak of the density function of the empirical asset returns is higher than in the normal case, while the peak of the density function in stable case also stretches across the area of central values.

The utility function's dependence on risk aversion coefficient was investigated by means of constructing the following linear regression function, which characterizes the correspondence between the difference in values of the

utility functions in normal and stable cases, $U_{normal}(c)$ and $U_{stable}(c)$, respectively, and the risk aversion coefficient c:

$$U_{stable}(c) - U_{normal}(c) = b_0 + b_1 \cdot c + \xi_1. \quad (58.7)$$

The numerical results for the portfolio of DowJonesIndustrials index and 3-month T-bill show that the predicted value of the utility functions difference have the following view:

$$U_{stable}(c) - U_{normal}(c) = 0.0087 + 0.8206 \cdot c, \quad (58.8)$$

where the *p-level* (or, statistical significance) is close to zero (0.037), which indicates that there is a small probability of error of assuming that the calculation result is "true".

The results given in the Table 58.1 results from extending the analysis described above to the additional time series. The results presented below describe the utility function's dependence on the risk aversion coefficient for the mentioned above portfolios.

The final analysis investigates the ratio of the risk aversion coefficients in normal and stable cases, where the optimal risk aversion coefficient (under condition of maximum utility and closeness of the simulated weights to the empirical weights) in the stable case is represented as a function of the corresponding risk aversion coefficient in normal case. The regression equation is the following:

$$c_{stable}^{opt} = b_0 + b_1 \cdot c_{normal}^{opt} + \xi_2. \quad (58.9)$$

The estimation of the regression coefficients in case of the DowJonesIndustrials index and 3-month T-bill portfolio produces the following result:

$$c_{stable}^{opt} = 0.0014 + 0.9907 \cdot c_{normal}^{opt}, \quad (58.10)$$

Table 58.1 Utility function dependence on risk aversion coefficient

| Portfolio | Period, days | $U_{stable}(c) - U_{normal}(c) = b_0 + b_1 \cdot c + \xi_1$ | | |
		b_0	B_1	p-level
DowJonesIndustrials and 3-month T-bill	1,563	0.0087	0.8206	0.037
24 assets of DAX30	1,387	0.0563	0.6972	0.093
DAX30 and 6-month EURIBOR	1,139	0.0098	0.9273	0.016
DAX30, CAC40 and 6-month EURIBOR	1,146	0.0352	0.9447	0.0047

Table 58.2 Dependence between risk aversion coefficients in stable and normal cases

| Portfolio | Period, days | $c_{stable}^{opt} = b_0 + b_1 \cdot c_{normal}^{opt} + \xi_2$ | | |
		b_0	b_1	p-level
DowJonesIndustrials and 3-month T-bill	1,563	0.0014	0.9907	0.0063
24 assets of DAX30	1,387	0.0332	0.8730	0.0258
DAX30 and 6-month EURIBOR	1,139	0.0022	0.9741	0.0057
DAX30, CAC40 and 6-month EURIBOR	1,146	0.0351	0.8413	0.0104

where the *p-level* = 0.0063, which also speaks for the statistical significance of the estimated values and, therefore, of the prediction.

Table 58.2 presents the estimation of the regression coefficients for the other portfolios.

To summarize, the results indicate that the risk aversion coefficient value in the stable case is significantly lower than in the normal one, i.e. $c_{stable}^{opt} << c_{normal}^{opt}$. The difference becomes more apparent for higher values of the risk aversion coefficient. Thus, we can conclude that under the assumption that portfolio asset returns follow the stable distribution results in lower risk aversion coefficients compared with the case of the normal distribution.

58.8 Conclusions

In this paper, we first briefly describe the stable distributions as an alternative approach to financial market investigation and its advantages compared with the normal distribution.

We propose a model for portfolio optimization under the assumption that portfolio asset returns are subject to the stable distribution. The comparison made between the stable and the normal approach in terms of the optimal allocation problem indicates that the stable distribution assumption for asset returns impacts the analysis in a meaningful way, as compared with the normal distribution. The stable approach considers that risk results from heavy tails. Thus the heavy tail behaviour of the stable distributed asset returns, compared with the normal case, greatly affects decision making in asset allocation. Since the stable distribution reflects better the financial market reality, better results in portfolio optimisation obtain under the stable distribution assumption.

Finally, we investigate the relationship between the maximum expected utility functions of an investor in stable and normal cases. We analyze the optimal risk aversion coefficients ratio obtained in both normal and stable cases. The analysis highlights significant differences in the stable and normal approaches, where the assumption of the stable distributed asset returns allowed for improvement on performance of the model.

Abstract

A reverse mortgage is a financial product that allows a senior homeowner to access their home equity. In contrast to a traditional or conventional "forward" mortgage, a reverse mortgage allows the borrower to draw on the equity in the home and only repay the loan when they vacate the house. This allows a borrower with few liquid assets but a lot of accumulated home equity to access trapped cash. The FHA's reverse mortgage program referred to as the Home Equity Conversion (HECM) program was established in 1989, though Ginnie Mae mortgage-backed securities backed by HECM's (HMBS) were issued for investors and the first Ginnie Mae H-REMIC (CMO) backed by multiple HMBS pools was not issued until 2009. The methods and parameters used to compute yields with varying LIBOR assumptions for CMO tranches backed by reverse mortgages differs from those for traditional mortgages.

59.1 Introduction

A reverse mortgage is a type of mortgage that borrowers, instead of paying the lender, will receive fixed or variable cash flow payments before the maturity date or when the home owner vacates the property used as collateral. The loan is only repaid if the property is sold or refinanced. A reverse mortgage is designed for senior home owners, 62 years of age or older, in the U.S. to maximize the duration of receiving payments against their properties. As baby boomers started to retire and the demographic pyramid gradually flattened, the eligible pool of borrowers for reverse mortgages increased in the past decade (see NRMLA Website). There are three types of reverse mortgages:

1. Single purpose reverse mortgages—these are offered only by some state and local government agencies and nonprofit organizations, like credit unions.
2. FHA insured reverse mortgages—also known as Home Equity Conversion Mortgages (HECMs) and backed by the US Department of Housing and Urban Development (HUD).
3. Private/Proprietary reverse mortgages—private loans, typically backed by the insurance or specialty finance companies that originate them.

Single purpose reverse mortgages are not available everywhere and can only be used for the purpose specified by the lender or the government, for example, a loan is made for repairs or property taxes only. The most popular type for U.S. seniors is the HECM program. The HECM is run by the U.S. Department of Housing and Urban Development through the Federal Housing Administration (FHA).

e-mail: ted@beyondbond.com

Fig. 59.1 FHA origination volume by initial principal limit (Source: FHA, Beyondbond, Inc.)
59.2 The FHA Home Equity Conversion Mortgage (HECM) Program

The FHA's HECM platform has a dominant market share in excess of 90% and is where we focus further analysis and discussion. The FHA's Home Equity Conversion Mortgage (HECM) program, which was piloted in 1989 and made permanent in 1998, allows older homeowners to withdraw some of the equity in their homes.

In addition, a HECM mortgage may be used to purchase a primary home when the borrower is 62 years of age or older and is able to use assets to fund the difference between the reverse mortgage and the sales price plus closing costs.

Unlike for a traditional forward mortgage, the HECM borrower does not make payments to the lender; rather, the lender makes payments to the borrower. A HECM mortgage allows a borrower to extract a portion of the equity in the home while continuing to live in the residence, and in that sense, a HECM resembles a Home Equity Line of Credit (HELOC). HECM loan origination has grown steadily since the program's inception in 1989. Figure 59.1 shows that annual loan origination has increased from $544 million in 2000, peaking at $21.7 billion in 2009, to $10.9 billion for 2011. Figure 59.2 adds the maximum claim about to the initial principal limit to the annual loan origination chart.

59.2.1 HECM Versus HELOC

A HECM mortgage allows a borrower to extract a portion of the equity in the home, while continuing to live in the residence, and in that sense, a HECM resembles a traditional or conventional Home Equity Line of Credit (HELOC). However, a HECM differs from a HELOC in the following ways:

- First, no principal repayment is required until the borrower no longer uses the home as a primary residence. Unlike a traditional HELOC, the payments are reversed,

so the principal payments flow from the lender to the borrower.
- Second, the borrower is required to use the house as the primary residence. Per FHA underwriting standards, the residence must be owner occupied.
- Third, a HELOC requires a sufficient debt-to-income ratio to service the loan and a combined LTV test as well as FICO score. Since the payments are reversed, lenders do not consider the borrower's debt to income ratio for a HECM or require a FICO.

59.2.2 Qualifications and Payment Plans

HUD has listed the FHA qualified borrower requirements and various payment plans for HECM summarized as the following table[1]: (see Ginnie Mae MBS Guide, 2011; HUD Handbook, 1994)

FHA Eligibility requirements	Borrow requirements	Payment plans
The borrower must be 62 years of age or older	The borrower must be 62 years of age or older	The Tenure option provides for equal monthly payments as long as at least one borrower lives and continues to occupy the home as his/her principal residence
Ownership of the property must be outright or a de minimus mortgage balance	Ownership of the property must be outright or a de minimus mortgage balance

FHA Eligibility requirements	Borrow requirements	Payment plans
borrower must participate in a consumer information session given by an approved HECM counselor	borrower must participate in a consumer information session given by an approved HECM counselor	borrower to draw (unscheduled payments) at times and in an amount of his/her choosing until the line of credit is exhausted
HUD-approved properties include single-family or 1–4 unit homes, condominiums and manufactured homes	HUD-approved properties include single-family or 1–4 unit homes, condominiums and manufactured homes	The Modified Tenure option is a combination of scheduled monthly payments as long as the borrower remains in the home and a line of credit
		The Modified Term option is a combination of scheduled monthly payments for a fixed time period and a line of credit

59.2.3 Loan Amount: Principal Limit; Maximum Claim Amount (MCA)

The amount of money the homeowner can borrow is known as the principal limit, and is calculated using a formula based on borrower's age, current interest rate level and home value (see Ginnie Mae MBS Guide 2011). As older borrowers are expected to accrue less interest, and therefore may borrow more. The lower interest rate environment obviously will lead to less interest accrued, and allow the homeowner to borrow more. The FHA has county-based lending limits based on borrower's location and home value. The amount available is based on the lesser of the home value and the FHA limit for the county. The national lending limit is $625,500.

It is important to note that the principal limit is less than the Maximum Claim Amount (MCA). The maximum claim amount is the largest amount that the FHA will insure for a given property, and is equal to the lesser of the home value and the local FHA lending limit. Since interest is capitalized, the principal can grow above the principal limit. However, when the principal nears the MCA, the FHA guarantee and put take effect.

59.2.4 Fees and Caps

FHA caps many of the up-front fees and rates associated with the HECM. For example: (1) Mortgage insurance premium (MIP): The borrower pays a MIP equal to 2% of the maximum claim amount (the value of the home or FHA county lending limit, whichever is less), plus an annual premium thereafter equal to 0.5% of the loan balance. The MIP is paid directly to FHA in exchange for guaranteeing the loan. The MIP guarantees that if the company managing the Borrower's account, either the servicer or issuer goes out of business, the government will step in and make sure the borrower has continued access to the borrower's loan funds. (2) Rate adjustment cap: In the case of an annually adjusting loan, the rate cannot increase more than 2% per year. However, in the case of a monthly adjusting loan, there is no annual cap. (3) Lifetime rate adjustment cap: In the case of an annually adjusting loan, the rate adjustment is capped at 5% over the initial loan rate at closing. In the case of a monthly adjusting loan, the cap is 10% over the initial loan rate at closing. (4) Servicing fees: Fees are capped at $30 per month for annually adjusted loans; $35 per month for monthly adjusted loans. A present value estimate of future service fees is set aside at closing based on the assumption the homeowner will live until the age of 100. (5) There is also an origination fee charged on every loan. These vary from lender to lender. Lenders usually allow borrowers to

Fig. 59.3 The HECM PPC by age (Source: FHA, Ginnie Mae)
finance the origination fee, and the FHA caps the fee at the greater of $2,000 or 2% of the MCA.

In addition to the fees above, the borrower will also pay other standard closing costs associated with getting a mortgage, including title insurance, attorney's fees, recording taxes, etc.

59.2.5 HECM Prepayment Curve (PPC)

The pricing convention in the HECM market is based on a prepayment curve (PPC vector). The HECM PPC ramp begins at 0.05% CPR and increases to 12% CPR in month 39. The PPC ramp continues to increase through month 360, reaching at peak at 43% CPR. The PPC ramp is also referred to as the FHA or HUD curve and is based on the prepayment experience of FHA HECM loans and is shown graphically in Figure 59.3 and complete details are included in Appendix 2.

59.2.5.1 Ginnie Mae HECM Pooling (HMBS)

The Government National Mortgage Association (Ginnie Mae) has created a HECM loan pooling program (HMBS) with the intent on providing liquidity to the reverse mortgage market. HECM MBS are backed by participation interests in advances made to borrowers and related amounts. As Ginnie Mae securities, HECM's share the following characteristics with other Ginnie Mae programs. First, Ginnie Mae reverse mortgage loans are insured by the Federal Housing Administration (FHA), and Ginnie Mae guarantees the timely payment of principal and interest on each class of securities. Second, the Ginnie Mae guarantee is backed by the full faith and credit of the United States. Third, HECMs are Ginnie Mae II securities and, as such, carry a 0% risk weighting for capital purposes.

HECM balances are funded at the time the borrower draws on his/her line of credit. Because the borrower may not draw the entire balance available at the time of loan closing, a single borrower may be represented in several HMBS pools or securitizations.

The issuer/servicer is also obligated to buy out any advance from a pool when the underlying loan reaches 98% of its MCA. This flows through to the investor as a prepayment, not as scheduled P&I. If the loan has become due, the servicer will continue to service the loan until the home is sold and the loan is liquidated. If there is any shortfall, the FHA guarantee will come into effect and the FHA will make the servicer whole.

If the loan has not become due, the loan can be assigned to the FHA, and the servicer is again made whole. This typically happens when a borrower stays in the home longer than expected. This is also referred to as the FHA put.

59.2.5.2 HECM Pool Characteristics

Similar to traditional forward mortgages, reverse mortgage pools will have aggregation-level data reported on them. These will include the (1) Single male, single female and couple ages, (2) Loan and property type, (3) Principal limit, (4) Ratio of outstanding balance to MCA, and (5) Ratio of outstanding balance to principal limit.

Similar to forward mortgage pass-throughs, there is both a note rate (rate paid by the borrower) and a pass-through rate (rate received and accrued to the security holder). The spread, which compensates both the issuer and Ginnie Mae, can range from 6 bps to 75 bps (see Rao, 2009; Ginnie Mae MBS Guide, 2011).

Ginnie Mae mandates that a pool be at least $1MM in original balance, and contain at least three HECM participations from three distinct HECM reverse mortgages.

59.2.5.3 Cash Flows and Prepayments

A reverse mortgage advance is similar to a zero-coupon bond to an investor, but has an uncertain maturity. The investor purchases the pool, and interest accrues until the borrower chooses to prepay, or the loan comes due. Borrowers are permitted to prepay their reverse mortgages at any time without penalty.

Fig. 59.4 Ginnie Mae
H-REMIC issuance (Source:
Ginnie Mae, Beyondbond, Inc.)
When a loan comes due, the borrower (or their estate) has 12 months to either sell the home or pay off the reverse mortgage with cash. The loan continues to accrue interest during this time.

Investors also get a prepayment when the principal balance on the HECM is equal to or greater than 98% of the MCA. At that point, as mentioned previously, the issuer is obligated to buy out all participations from that HECM (most likely in multiple securities). Since the accrued interest is added on to the loan principal, any mortgage will eventually reach this limit.

Historically, 90% of reverse mortgages are paid off through the sale of the home, refinancing, or with cash (see Patterson et al, 2007). 9% of loans are bought out by the lender and assigned to the FHA. The remaining 1% requires the FHA to step in and pay a claim because the proceeds of the home sale were not enough to cover the loan.

Also, it is important to note that because interest is capitalized into the loan, every HECM will eventually be bought out by the issuer even if there is no maturity event. According to HUD's data, 58% of HECMs terminate or are assigned within 7 years, and 100% of HECMs terminate or are assigned within 18 years. Thus, even though a HMBS may have a stated final maturity of 50 years, it is very unlikely that any participation will remain in the pool after even half that time.

59.2.5.4 H-REMIC Tranche Principal Types

HMBS can be further aggregated and structured in the form of a Reverse Mortgage CMO or H-REMIC. An H-REMIC provides for additional diversification as well as specific tranching of cashflows for specific investor needs (see Schultz and Ahlgren, 2010). Figure 59.4 shows similar growth in the H-REMIC monthly issuance since inception. As described in Figure 59.5, there are currently three principal bond types in an H-REMIC:
Fig. 59.5 Ginnie Mae H-REMIC tranche principal types (Source: Ginnie Mae, Beyondbond, Inc.)

- HECM MBS Pass-Through Class: A HECM MBS Pass-Through Class ("HPT") is a Class that is backed in whole or in part by Trust Assets consisting of HECM MBS that either individually or together with other Classes receives on each Distribution Date all, or substantially all, of the principal and/or interest payments received on the related Trust Assets and that is not a Strip or HECM MBS Sequential Pay Class.
- HECM MBS Sequential Pay Class: A HECM MBS Sequential Pay Class ("HSEQ") is a Class that is backed in whole or in part by Trust Assets consisting of HECM MBS that receives distributions of principal in a prescribed sequence, that do not have predetermined

schedules and that generally are designed to receive distributions of principal continuously from the first Distribution Date on which they receive principal until they are retired. A HECM MBS Sequential Pay Class may receive principal distributions concurrently with one or more other HECM MBS Sequential Pay Classes.

• Notional Classes: The Notional Classes ("NTL") will not receive distributions of principal based on their Class Notional Balances but have Class Notional Balances for convenience in describing their entitlements to interest.

59.2.6 H-REMIC Modeling Example: GNR 2011-H10

We will analyze a Ginnie Mae Reverse Mortgage CMO/H-REMIC, GNR 2011-H10 (see Ginnie Mae REMIC Offering Circulars, 2010), using the Beyondbond, Inc. proprietary reverse mortgage cashflow modeling analytic system.

The Issuer (Ginnie Mae), Dealer and Accountant must tie out all aspects of the computations contained in the Prospectus Supplement, which includes Weighted Average Life, Decrement (DEC) Tables, and Price-Yield Tables.

Because of the complexity in the modeling of cashflows, certain standard modeling assumptions are made.

59.2.6.1 Assumptions for GNR 2011-H10

The tables that follow have been prepared on the basis of the following assumptions (the "Modeling Assumptions"), among others:

1. The HECMs and related Participations underlying the Trust Assets have the assumed characteristics shown in the Beyondbond, Inc. Collateral Viewer in Figure 59.6 and further detailed in Appendix 1.

2. The HECMs prepay at the constant percentages of the prepayment curve (show in Figure 59.3) shown in the related table in Appendix 2.

3. Draw activity occurs on the first day of the month and payments on the HECMs occur on the last day of the month, whether or not a Business Day, commencing in April 2011.

4. Distributions, if any, on the Securities are always received on the 20th day of the month, whether or not a Business Day, commencing in May 2011.

5. A termination of the Trust does not occur.

6. The Closing Date for the Securities is April 29, 2011.

7. No expenses or fees are paid by the Trust other than the Trustee Fee.

8. HECM borrowers who have the ability to do so draw at the annualized draw rate determined in accordance with the constant percentages of the draw curve shown in Exhibit C (the "Draw Rate"). The Draw Rate (converted to an equivalent monthly factor) is applied to the Maximum Claim Amount.

9. If a mandatory Ginnie Mae Issuer Purchase Event occurs with respect to a HECM, the purchase of the related Participation timely occurs. No optional Ginnie Mae Issuer Purchase Events occur.

10. The initial value of LIBOR on the Securities is 0.26%; however, the interest rate on the adjustable rate HECMs for the first Distribution Date is based on the information

Class of REMIC	Principal Balance	Interest Rate	Principal Type	Interest Type	CUSIP Number	Final Distribution Date
AF	225,965,045	Adjustable	HPT	FLT/HWAC/HZ	38375BLJ9	August 2060
IF	225,965,045	Adjustable	NTL(HPT)	HWAC/IO/DLY	38375BLK6	August 2060
RR	0	0	NPR	NPR	38375BLL4	August 2060

Fig. 59.7 GNR 2011-H10 deal viewer (Source: Beyondbond, Inc.)

set forth in Exhibit A. On all Distribution Dates occurring after the first Distribution Date, the value of LIBOR on the adjustable rate HECMs is assumed to be the same as the value of LIBOR on the Securities. For purposes of the decrement tables, on all Distributions Dates occurring after the first Distribution Date the constant value of LIBOR shown with respect to any decrement table is used to calculate the interest rate with respect to the adjustable rate HECMs and to the applicable Class.

11. The original term of the HECMs is 50 years.
12. No borrower changes payment plans.
13. Draws occur each month in respect of the Monthly Servicing Fee, if any, as set forth on Exhibit A. No draws occur in respect of any set asides for property charges (such as taxes, hazard insurance, ground rents or assessments) or repairs.

When reading the tables and the related text, investors should bear in mind that the Modeling Assumptions, like any other stated assumptions, are unlikely to be entirely consistent with actual experience.

For example, most of the HECMs will not have the characteristics assumed, many Distribution Dates will occur on a Business Day after the 20th of the month, draw activity and prepayments, if any, will occur throughout the month, draws will occur in respect of set asides for property charges and repairs, the Trustee may cause a termination of the Trust as described under "Description of the Securities —Termination" in this Supplement and LIBOR on the Class AF Securities may differ from LIBOR on the adjustable rate HECMs.

In addition, distributions on the Securities are based on Certificate Factors and Calculated Certificate Factors, if applicable, which may not reflect actual receipts on the Trust Assets.

59.2.7 Payment Rules and Tranche Waterfall

Each class in the prospectus is described as the following Figure 59.7 for the REMIC class name, principal and interest types, annualized interest rate level (Interest Rate), initial certificate balance (Principal Balance), CUSIP, and schedule date of final payment received (Final Distribution Date)[2].

On each Distribution Date, the cashflow distribution of each REMIC class received from the HMBS certificates is referred to as the payment rules or tranche waterfall. The Available Distribution Amount will be allocated in the following order of priority[3]:

1. Concurrently, to AF and IF, pro rata based on their respective Interest Accrual Amounts, up to the Class AF Interest Accrual Amount and the Class IF Interest Accrual Amount for such Distribution Date
2. To AF, in reduction of its Class Principal Balance, up to the amount of the Class AF Principal Distribution Amount for such Distribution Date, until retired
3. To IF, until the Class IF Deferred Interest Amount is reduced to zero

59.2.7.1 Analysis

Cashflows are generated for each individual HMBS in various scenarios. Initially, absent any payoff events (0 PPC), no cashflows are paid to the H-REMIC classes and the interest is capitalized as displayed in the Cashflow Viewer in Figure 59.8, compared with the Cashflow under prepayment assumption at 100 PPC.

HMBS has historically traded at premiums to par as mortgages have higher spreads than typical LIBOR bonds. Due to investors' preference for par floating rate bonds, H-REMICs are able to strip off the spread premium by tranching an HMBS pool into a par floater, Class AF and an excess interest floater, Class IF. In the case of GNR 2011-H10, the underlying HMBS was trading at a premium of 105–106%. Class AF was issued at price of 100% and Class IF was then issued at a price of 5.5% (see Schultz, 2010).

As a par floater pass-thru, Class AF shows stability in yields in Figure 59.9, despite changes in prepayment rates and only variability due to changing LIBOR. This is desirable to investors as LIBOR can we readily hedged or directly moves in line with funding costs and is self-hedging.

In contrast to Class AF, which owes its yield stability to the fact that it receives both principal and interest, Class IF has a much more volatile yield pattern, as it only receives interest payments. Class IF could also be characterized as the premium component of the HMBS pass-thrus. Class IF appeals to an investor with a bearish view on repayments (bullish view on Borrowers longevity) or Administration healthcare initiatives (see Alexander, 2008) (Figure 59.10).

59.2.7.2 Conclusions and Further Study

Our analysis focuses on computing yields with varying HECM PPC and LIBOR assumptions for Ginnie Mae

Reverse Mortgage H-REMIC (CMO) tranches as typically disclosed to investors in a Prospectus Supplement. Further study should explore evolving actuarial data to explore the influence on prepayment rates of borrower age, gender, product type and geography for both FHA and Private loans.

In Appendix 4, we describe a way to estimate repayment rates from the existing US Life Tables (see Rai, 2009) for mortality and mobility, however, Reverse Mortgages in some cases are being utilized in the Make Home Affordable (MHA) initiatives to help keep Senior Borrowers in their homes and avoid foreclosures (see Strand and Deb, 2010). Any MHA or Administration initiative could structurally change the parameters for estimating prepayments.

Glossary (see Ginnie Mae MBS Guide, 2011; NRMLA website)

Reverse Mortgage Reverse mortgage loans are FHA-insured loans designed specifically to permit senior citizens to convert the home equity of their principal residence into cash.

HECM Home Equity Conversion Mortgages program. HECM was launched in 1987 by the Department of Housing and Urban Development. This is a federal

Fig. 59.10 GNR 2011-H10 Class IF Yield Table (Source: Beyondbond, Inc.)

reverse mortgage program and was launched to provide an opportunity to senior citizens to take advantage of their built-up home equity. The loans are fully guaranteed by the US government.

HMBS Home Equity Conversion Mortgage Backed Security. It's collateralized by HECM loans.

H-REMIC HECM Real Estate Mortgage Investment Conduit. Allows for inclusion of HMBS and forward Ginnie Mae MBS collateral within the same REMIC structure. First HREMIC Issuance: Anticipated January 2008.

HUD Department of Housing and Urban Development. Congress created the HECM program in 1989 and appointed the Department of Housing and Urban Development (HUD) as the administrator.

MIP Mortgage Insurance Premium. The borrower will be charged mortgage insurance premiums to reduce the risk of loss in the event that the outstanding balance, including accrued interest, MIP, and fees, exceeds the value of the property at the time that the mortgage is due and payable. HUD will select an agent to collect MIP.

MCA Maximum Claim Amount. The amount that FHA will insure for any HECM loan. FHA allows Issuers to assign a HECM loan that accrues to 98% of the MCA. Ginnie Mae requires any loan that has accrued to 98% of MCA to be purchased out of an HMBS pool whether or not an Issuer assigns the loan to FHA.

Appendix 1: Assumed Trust Assets GNR 2011-H10: HMBS Pools (see Ginnie Mae REMIC Offering Circulars 2010)

Appendix 2: HECM PPC Curve: CPR Percentage in Effect by HECM Age

Appendix 3: Example of Cashflow Payment Rules

(t starts from 1)

$$Rate_t(FA) = Min(Cap, LIBOR_t + Margin)$$

$$Accrue\ Interest_t(FA) = Balance_{t-1}(FA) \times Rate_t(FA)/12$$

$$(If\ Bond\ Principal_t \geq 0)$$

$$Interest_t(FA) = \frac{Bond\ Interest_t \times Accrue\ Interest_t(FA)}{Bond\ Interest_t}$$

Appendix 4: A Model for Estimating Repayment Speeds for HECMs

It is possible to estimate the repayment speeds on reverse mortgages by combining the mortality rates and mobility rates provided by the US Life Tables (see Rai, 2009). The probability that a borrower will not die in the next 12 months, at any given age, can be represented by (1 – Mortality Rate [Annualized]). Similarly, the probability that a borrower does not move out in the next 12 months is equal to (1 – Mobility Rate [Annualized]).

Thus, the probability that the loan does not repay over the next 12 months is equal to:

$$(1 - Mortality\ Rate)\ *\ (1 - Mobility\ Rate)$$

Therefore, the repayment speeds on reverse mortgages can be calculated as:

$$CPR = 1 - [(1 - Mortality\ Rate\ [Annualized])\ *$$
$$(1 - Mobility\ Rate\ [Annualized])]$$

Estimating repayments based on just mortality and mobility rates provides reasonable results, though the model will tend to overestimate repayment speeds as compared to the repayment speeds based on historical data, due to self-selection. Borrowers who are in good health are more likely to take out reverse mortgage loans despite high origination costs.

An Analysis of Risk Treatment in the Field of Finance

60

Fernando Gómez-Bezares
and Fernando R. Gómez-Bezares

Abstract

This paper studies the way to introduce risk into financial analysis. It suggests and analyzes metrics to improve the classic methods, like the Sharpe and Treynor ratios or the Net Present Value.

In particular, the paper suggests a linear penalization method developed by the authors, applying it to performance indexes and capital budgeting, and considering both total and systematic risk. The method shows obvious advantages in comparison with traditional methods.

Keywords

Capital budgeting • Linear penalization • Performance • Risk

60.1 Introduction

It has been generally accepted[1] in the field of finance that individuals are risk averse. This implies that risk must be considered in order to value an asset or to measure the performance of an investment. In short words, those assets that are riskier need to have a higher return (on average) to be considered an attractive investment. Both the way in which risk is measured and how to introduce it as an input into analyses have been key subjects of financial research, this has been particularly true since the middle of the twentieth century.

Indeed, the risk problem has been widely studied in financial literature, where we can mention the State-Preference Theory[2] as a general framework. However, in the fields of stock market performance and capital budgeting

techniques, the most applied models until now are those derived from the Portfolio Theory,[3] like the Capital Asset Pricing Model (CAPM)[4] of Sharpe (1964), Lintner (1965), Black (1972)...

This paper brings up a clear problem that appears on performance indexes as commonly used as Sharpe's or Treynor's, questioning the classifications they make. We think that the root of the problem is to use the quotient to penalize for risk, suggesting the linear penalization as an alternative. This gives birth to a new system of performance measuring, the PIRR, which in one of its versions is equivalent to Jensen's α index.

Classic performance indexes, like Sharpe's, Treynor's and Jensen's, have been and currently are widely applied both by practitioners (in their asset management) and by academics (in their research). Just to quote a few, authors like Chua and Koh (2007) apply Sharpe; Hodges et al. (2003) apply Treynor; Sainz et al. (2006) or Fama and French (2010) apply Jensen; Yu and Liow (2009), Benefield et al. (2009), Lipton and Kish (2010) or Mazumder et al. (2010) apply several of these indexes in varied contexts. Also can be mentioned: Collins

[3] Markowitz (1952, 1959).

[4] Although asset valuation models based on real options are also being increasingly applied for the last years, we are not entering here into their discussion.

and Fabozzi (2000), In et al. (2008), Chu and McKenzie (2008), Lee et al. (2009) or Ho et al. (2011). This shows the relevance of present paper, as it develops advantageous alternatives to Sharpe's and Treynor's indexes, suggesting as well an improvement in Jensen's index.

In our opinion, indexes must be easy to calculate, and above all easy to understand. This is why we suggest very practical indexes that besides are measured in returns (this is one of the advantages of Modigliani and Modigliani's index despite it matches its classification with Sharpe's index). On the other hand, our proposed indexes avoid the problems before mentioned. Of course that linear penalization also has some problems, but we consider them less important, as we will explain later.

The linear penalization system can also be extended on to NPV with a clearly original development, giving rise to the PPV,[5] which is commented within the paper.

In this work we are not going to question the hypothesis of whether individuals are risk averse, neither the way to measure this risk[6] (total or systematic risk within the CAPM framework). What we are going to discuss is the way in which risk must be introduced into analyses. With this goal, we will start by reviewing the investment classification implied by the Sharpe and Treynor ratios, and we will suggest an alternative method. We will also analyze how to penalize the Net Present Value, ending with some conclusions.

60.2 Sharpe's Classification

When measuring the performance of a portfolio, and presuming its liquidity, we must consider return and risk. Within the context of the Portfolio Theory, we will understand risk as variability, and we will measure it with the standard deviation. This is more justifiable assuming a normal distribution of returns, as the normal distribution is defined with the mean[7] (μ) and standard deviation (σ) parameters. This approach is consistent with Sharpe (1966), who suggests classifying portfolios according to their performance with the following ratio:

$$ S = \frac{\mu - r_0}{\sigma} \qquad (60.1) $$

---

[5] The NPV is considered, in a classic reference in finance, as is Brealey et al. (2008), as the first one of the seven most important ideas in finance. In order to introduce risk into the NPV, the most widely applied systems are the *risk-adjusted rate of return valuation formula* and the *certainty equivalent valuation formula* (Copeland et al., 2005, pp. 156–157). We will use an alternative system, derived from the NPV: the *Penalized Present Value (PPV)*.

[6] Although both subjects have been and will be topic of discussion.

[7] Expected value.
Fig. 60.1 Figure 60.1 shows the Capital Market Line and values of the Sharpe ratio and the PIRR

Where μ and σ are the mean and standard deviation of portfolio returns, and r_0 is the risk-free rate. Assuming a map on $\mu - \sigma$ axes, where μ_m and σ_m are the mean and standard deviation for the Market Portfolio returns (R_m), and within the framework of the Portfolio Theory, we find the Capital Market Line (CML) of Figure 60.1. We can also identify portfolios R_a and R_b with their respective means and deviations. It is easy to confirm that the tangents of the α angles in this figure are the respective Sharpe ratios of the three portfolios.[8]

The Sharpe ratio is undoubtedly one of the most employed indexes in the financial industry, and its portfolio classification coincides with the ranking that we can derive from the M^2 suggested by Modigliani and Modigliani (1997). However, it has a significant flaw: presuming normal distributions of returns, Sharpe classifies portfolios on the basis of their probability of giving a return below r_0, which is easy to verify simply by looking at formula (60.1). We consider that in many cases this ranking cannot be supported: a portfolio π may have a much higher μ than another portfolio φ, but if φ had a slightly smaller probability of giving a return below r_0, it would be classified with Sharpe or M^2 better than π, despite the fact that nearly always π will give much higher returns than φ.

The following example illustrates this flaw of the Sharpe ratio:

We can assume that we have two investment funds, "A" and "B", with the following mean (μ) and standard deviation (σ) for their returns:

$$ \mu_A = 30\% \qquad \sigma_A = 9\% $$
$$ \mu_B = 7\% \qquad \sigma_B = 1\% $$

---

[8] And we will explain later the meaning of the PIRR.

If the risk-free rate is $r_0 = 3\%$, the Sharpe ratios for these investment funds are:

$$S_A = (30 - 3)/9 = 3 \qquad S_B = (7 - 3)/1 = 4$$

Following the Sharpe ratio, "B" investment fund is better, as its S is higher. If we assume that returns follow a normal distribution, the probability of "B" giving a return below the risk-free rate (3%) is 0.00003. The same probability for "A" is 0.00135. As Sharpe ranks investments minimizing this probability, then $S_B > S_A$.

However, it seems quite clear that common investors would prefer "A" investment fund. In fact, **with a probability of ~99.5%, the returns of "A" investment fund will be higher than the average return of "B" investment fund**. Therefore, in this type of cases, Sharpe's ratio would be misleading to take investment decisions.[9]

60.3 Treynor's Classification

Starting from the well-known differentiation between systematic and diversifiable risk:

$$\sigma_j^2 = \beta_j^2 \ \sigma_m^2 + \sigma_\varepsilon^2 \qquad (60.2)$$

Where we can read: the total risk of portfolio j (measured here as the variance of its returns) is equal to the square of its beta multiplied by the market variance, plus the variance of ε (that represents diversifiable risk). Assuming now that the portfolio whose performance we are measuring will be integrated into a wider and well diversified portfolio, the variance of ε can be disregarded (as diversification will make it null), and we can measure the risk with beta.[10] This leads us to the Treynor (1965) ratio[11]:

$$T = \frac{\mu - r_0}{\beta} \qquad (60.3)$$

Where beta is the measure of systematic risk in the CAPM. In Figure 60.2, quite similar to number 60.1, we find the Security Market Line (SML), in a CAPM μ-β map, where we
Fig. 60.2 Figure 60.2 shows the Security Market Line and values of the Treynor ratio and the PIRR for beta

can see how the Treynor ratio of each portfolio is also measured as the tangent of its respective α angle.[12]

If we now replace formula (60.2)[13] in formula (60.1), and disregarding the variance of ε[14]:

$$S = \frac{\mu - r_0}{\sqrt{\beta^2 \ \sigma_m^2 + \sigma_\varepsilon^2}} \approx \frac{\mu - r_0}{\sqrt{\beta^2 \ \sigma_m^2}} = \frac{\mu - r_0}{\beta \ \sigma_m}$$

$$= \frac{T}{\sigma_m} \qquad (60.4)$$

Considering that σ_m is equal for every portfolio, Sharpe and Treynor would lead us to the same ranking, and this is what happens for well diversified portfolios.

We can go further and assume that a non-diversified portfolio whose performance we are measuring is going to be integrated into a wider and well diversified portfolio, and that consequently the diversifiable risk will disappear.[15] In this case, the probability of giving a return below r_0 (which is measured by Sharpe as we mentioned above) will only depend on beta.[16] **We can thus say that Treynor also ranks portfolios according to their probability of giving a return below r_0, and we have already criticized this.**

---

[9] It might be argued that somebody could, by borrowing money at the risk-free rate, start from "B" and reach an investment that outperformed "A", and this is true. However, small investors cannot get themselves into debt at the risk-free rate. Besides, the performance of an investment fund is known ex-post, and by then, it is impossible for any investor to leverage his or her investment.

[10] As the market variance will be equal for all the portfolios.

[11] The classification obtained is the same as with M^2 for beta (Modigliani, 1997).

[12] We will explain the PIRR for beta later.

[13] Dispensing here with the j subindex.

[14] For this reason we are employing the $\approx$ symbol.

[15] This would allow to measure risk with β and the use of Treynor.

[16] Out of the components of total risk, the diversifiable risk will disappear, and the market standard deviation is the same for every portfolio. Therefore, the only difference will be β.

60.4 Advantages of Linear Penalization: PIRR and PIRR for Beta

The paradoxes identified in Sharpe's and Treynor's indexes come from applying a system of risk quotient penalization. Gómez-Bezares (1993) suggested a linear penalization system that was applied to the case we are facing by Gómez-Bezares et al. (2004). The Penalized Internal Rate of Return (**PIRR**) is calculated by deducting t standard deviations (σ) from the expected return (μ) of the analyzed portfolio:

$$\text{PIRR} = \mu - t\,\sigma \qquad (60.5)$$

The PIRR value is a performance metric that should be interpreted as a certainty equivalent for a portfolio with risk, being therefore useful to compare the risk-adjusted performance of different portfolios. The return premium asked for each risk unit would be t, and can be understood as given by the market: t would be the market Sharpe (the tangent of α_m in Figure 60.1). In fact, replacing the parameters of the market portfolio in Equation 60.5 we get to $\text{PIRR}_m = r_0$. In consequence, r_0 would be the certainty equivalent of the market portfolio, this should be interpreted by saying that individuals, on average, are indifferent between r_0 and R_m, which seems very reasonable.[17]

On the other hand, and assuming normal distributions, t has a clear statistical meaning: for a t value, the PIRR would be the guaranteed minimum return with a determined probability (that would depend on t value). This system is equivalent to the use of parallel indifference straight lines, as can be confirmed in Figure 60.1, where can also be seen that in this case the portfolio classification derived from the use of the PIRR differs from that one derived from Sharpe.[18]

Therefore, the PIRR consists of a different system to Sharpe's index, despite both methods consider the total risk of investments.

We can see now what happens when applying the PIRR to the same example we developed in Section 60.2. Assuming t = 1 we will have (values in %):

$$\text{PIRR}_A = 30 - 9 = 21$$
$$\text{PIRR}_B = 7 - 1 = 6$$

Being "A" investment fund clearly better, which is the same conclusion that mere common sense suggested. From a statistical point of view, assuming a normal distribution of returns, a value of t = 1 leaves a probability of 0.15866; therefore, in this case, the calculated PIRR is a guaranteed minimum return with a probability of 0.84134. As mentioned before, it is very logical to take the market Sharpe as t value, but investors could be occasionally more demanding.

Supposing now that the diversifiable risk can be disregarded, and using as t the Sharpe of the market, we will get to the following expression:

$$\begin{aligned}
\text{PIRR} = \mu - t\,\sigma &= \mu - \frac{\mu_m - r_0}{\sigma_m}\,\sigma \\
&= \mu - \frac{\mu_m - r_0}{\sigma_m}\sqrt{\beta^2\,\sigma_m^2 + \sigma_\varepsilon^2} \\
&\approx \mu - (\mu_m - r_0)\,\beta \qquad (60.6)
\end{aligned}$$

The PIRR obtained in Equation 60.6 can be named **PIRR for beta**, and this would be the performance metric alternative to Treynor. Its functioning can be seen in Figure 60.2, and much of what has been said when comparing the PIRR with Sharpe can here be repeated and adapted. PIRR for beta leads us to the same portfolio classification as the Jensen α (1968, 1969).

Therefore, both PIRR and PIRR for beta have the following advantages in comparison with Sharpe's and Treynor's indexes respectively:

1. Their values can be **easily interpreted** as a certainty equivalent of average return, with the degree of confidence that investors want to demand in order to take their investment decisions. These return values measured by PIRR and PIRR for beta are much easier to understand by an average investor.
2. These metrics based on linear penalization **avoid the risk shown in the example** of **Section 60.2**, and do not rank investments by their probability of giving a return below r_0.

---

[17] It could also be reasoned in this way: the market Sharpe, which is the slope of the CML, shows the "price of risk", which is the increase in the expected return that is demanded for a risk increase. Consequently, it is logical to give such a value to t in the formula (60.5).

[18] The use of indifference straight lines is a constraint of the system, which can be mitigated by the use of increasing t values as the risk grows. Sharpe also employs indifference straight lines, but instead of being parallels, they form a beam.

In Figure 60.1, following the Sharpe ratio, all the portfolios located on the same straight line starting from r_0 would be indifferent. For example, if we focus on the straight line linking r_0 and R_a, and according to the Sharpe ratio, all the portfolios on this straight line are indifferent to R_a, because their Sharpe value is the same: the tangent of α_a. At the same time, these portfolios would be worse than those located on the straight line linking r_0 and R_b, because the latter ones have a higher Sharpe. This is the consequence of Sharpe using a system of indifference straight lines forming a beam.

In the case of the PIRR system, indifference straight lines are drawn in parallel to the CML. The crossing point with the vertical axis is the PIRR, and its value is bigger the higher the straight line crosses with the vertical axis.

If we applied increasing t values, as it was mentioned before, we would get closer to obtain indifference curves and we could reach to a solution quite similar to the standard one.

Therefore, there are clear differences between the PIRR and the Sharpe ratio, and also between the PIRR for beta and the Treynor ratio. In the case of Jensen α, it classifies investments in the same way as the PIRR for beta does, but the PIRR for beta value is once again easier to interpret. The PIRR method is being applied lately, as it can be seen in Ferruz et al. (2009, 2010).

60.5 Penalized Present Value

The Penalized Present Value (PPV) suggested by Gómez-Bezares (1993) is based on Net Present Value[19] (NPV), and penalizes μ_{NPV} (expected NPV) according to σ_{NPV} in order to use this result as a decision criterion.

$$PPV = \mu_{NPV} - t\ \sigma_{NPV} \qquad (60.7)$$

This is a certainty equivalent, on which similar considerations can be made to those already set out for the PIRR.[20]

Assuming now a unique period of time, and investing an amount I into project i (with expected return μ_i and risk σ_i), we will get to:

$$\mu_{NPV}\,(i) = \frac{I(1 + \mu_i)}{1 + r_0} - I = I\frac{\mu_i - r_0}{1 + r_0} \qquad (60.8)$$

The standard deviation of NPV will be σ (of return), multiplied by the investment and discounted at the risk-free rate. It is easy to see what the result is when the investment return is r_0, in this case μ_{NPV} would be zero. We can transform Figure 60.1, making a scale change in the vertical axis, so that appears μ_{NPV} and we get to Figure 60.3. The PPV$_i$ will be calculated deducting from μ_{NPV} the slope that now has the CML multiplied by σ_i. We see in Equation 60.9 that these operations result in μ_{NPV} minus the market Sharpe multiplied by σ_{NPV}.[21]

$$PPV(i) = I\frac{\mu_i - r_0}{1 + r_0} - \frac{I\frac{\mu_m - r_0}{1 + r_0}}{\sigma_m}\ \sigma_i$$
$$= I\frac{\mu_i - r_0}{1 + r_0} - \frac{\mu_m - r_0}{\sigma_m}\ \sigma_{NPV} \qquad (60.9)$$

Fig. 60.3 Figure 60.3 shows the Penalized Present Value (PPV)

We can also see PPV$_i$ as σ_{NPV} $\{\sigma_{NPV} = I.\sigma_i/(1 + r_0)\}$ multiplied by the difference of Sharpes: first half of Equation 60.10. In the second half of Equation 60.10 we find (between square brackets) the difference between the obtained premium and the expected premium according to the CML of Figure 60.1. Multiplying this extra premium by I, and discounting at the risk-free rate, we also get to PPV$_i$.

$$PPV(i) = \sigma_{NPV}\left(\frac{\mu_i - r_0}{\sigma_i} - \frac{\mu_m - r_0}{\sigma_m}\right)$$
$$= \frac{I}{1 + r_0}\left[(\mu_i - r_0) - \frac{\mu_m - r_0}{\sigma_m}\ \sigma_i\right] \qquad (60.10)$$

Making in the vertical axis of Figure 60.2 a scale change like the one applied between Figures 60.1 and 60.3, we will get to Figure 60.4, where we find the PPV for beta. Starting from the first half of Equation 60.9, if we disregard the diversifiable risk, we will have:

$$PPV \text{ for beta (i)} = I\frac{\mu_i - r_0}{1 + r_0} - I\frac{\mu_m - r_0}{1 + r_0}\ \beta_i$$
$$= \frac{I}{1 + r_0}[(\mu_i - r_0) - (\mu_m - r_0)\ \beta_i] \qquad (60.11)$$

This can also be read in Figure 60.4 as μ_{NPV} minus the slope of SML multiplied by beta. In the second half of Equation 60.11 we find the extra return premium obtained,[22] which multiplied by I and discounted at the risk-free rate also gives the PPV for beta.

---

[19] Discounted at the risk-free rate, as the risk penalization is applied afterwards.

[20] Use of indifference straight lines, statistical meaning of t... Regarding t value, it should grow with the investment period as well as the market Sharpe tends to do so.

[21] Here, as in some other occasions, we dispense with i subindex for NPV, not to make notation more complicated.

[22] This is the Jensen α.
Fig. 60.4 Figure 60.4 shows the Penalized Present Value (PPV) for beta

The β_{NPV} will be equal to β_i multiplied by I and discounted at the risk-free rate:

$$\beta_{NPV}(i) = \frac{\sigma_{NPV,m}}{\sigma_m^2} = \frac{\sigma_{i,m}}{\sigma_m^2} * \frac{I}{1+r_0} = \beta_i \frac{I}{1+r_0} \quad (60.12)$$

Where $\sigma_{i,m}$ is the covariance between i return and market return. It can be deduced from the first half of Equation 60.11 that:

$$\begin{aligned} PPV \text{ for beta } (i) &= I\frac{\mu_i - r_0}{1+r_0} - I\frac{\mu_m - r_0}{1+r_0} \ \beta_i \\ &= \mu_{NPV}(i) - (\mu_m - r_0) \ \beta_{NPV}(i) \end{aligned}$$
$$(60.13)$$

This coincides with the classic certainty equivalent valuation formula.[23]

60.6 Final Thoughts and Conclusions

This paper presents two models of linear penalization of returns that may be of use (one model with σ and another one with β), as well as the penalization of NPV. It also shows the consistency between models in a way that we consider very original.

The system of linear penalization is an interesting alternative to Sharpe's or Treynor's indexes, as its output **can be easily interpreted as a certainty equivalent, and avoids certain mistakes in performance evaluation that Sharpe or Treynor ratios could cause.**

However, it is known that in this type of models the most correct option is to use indifference curves. In this sense, our model is a simplification, as it uses straight lines. This criticism may also be applied to the Sharpe and Treynor ratios, as

they use a beam of indifference straight lines and consider indifferent all those portfolios placed on the same straight line. Such criticism can be mitigated in our PIRR model by applying increasing "t"s, and therefore getting closer to use indifference curves. Working on this, we could face other potential criticisms related to the use of parallel indifference straight lines, because it is not the same to beat the CML (or the SML) in a certain amount for a low risk than for a high risk, being easier in the latter this extraordinary performance to be by chance. We consider that practicality and simplicity of use of the developed models should be important targets to consider, and this is why we think that proposed simplifications would be appropriate in many occasions.

Applying this methodology to asset valuation, the PPV may be an interesting criterion for capital budgeting with risk. In this paper is explained in more detail its application for a single investment period, but it can also be generalized to n periods. An elementary way to do so could be assuming reinvestments at the risk-free rate, therefore converting a case of n periods into a single period case.

Within this paper, it has been assumed that penalization "t" value was given by the market. However, this "t" value could be modified by the analyst, and then all the proposed methods would have new possibilities. Applying this option to the PPV would be particularly interesting.

The Trading Performance of Dynamic Hedging Models: Time Varying Covariance and Volatility Transmission Effects

61

Michael T. Chng and Gerard L. Gannon

Abstract

In this paper, we investigate the value of incorporating implied volatility from related option markets in dynamic hedging. We comprehensively model the volatility of all four S&P 500 cash, futures, index option and futures option markets simultaneously. Synchronous half-hourly observations are sampled from transaction data. Special classes of extended simultaneous volatility systems (ESVL) are estimated and used to generate out-of-sample hedge ratios. In a hypothetical dynamic hedging scheme, ESVL-based hedge ratios, which incorporate incremental information in the implied volatilities of the two S&P 500 option markets, generate profits from interim rebalancing of the futures hedging position that are incremental over competing hedge ratios. In addition, ESVL-based hedge ratios are the only hedge ratios that manage to generate sufficient profit during the hedging period to cover losses incurred by the physical portfolio.

Keywords

Volatility transmission • Dynamic hedging • Optimal hedge ratio • S&P 500

61.1 Introduction

The size of a hedge is affected by the sensitivity of the return of the underlying asset to the return of the hedging instrument. This sensitivity measure β is also called the optimal hedge ratio (OHR). The hedge ratio is deemed optimal in terms of minimizing the variability in the value of the overall position. A dynamic hedging scheme recognizes that since the OHR varies over time i.e. $\beta = \beta_t$, the hedging outcome can be improved from interim rebalancing of the hedging position. An issue addressed by the hedging literature is the incremental performances of competing OHRs over a static hedge. If the corresponding variance and covariance terms used to calculate the OHR can be adequately modeled and forecasted, then hedging performance should improve.

The volatility literature contains a voluminous debate on the information content of implied volatility versus historical volatility. The general consensus is that some combination of both improves volatility forecasts. Our main objective in this paper is to formally blend the two literatures together. We investigate if incremental information from combining implied and historical volatilities translates into incremental hedging performance by the corresponding OHR. We consider the use of the S&P 500 index futures (henceforth FI) contract to hedge against a widely-held portfolio that tracks the S&P 500 index e.g. S&P Depository Receipts (SPDR). In this paper, we assume the S&P 500 cash index (henceforth CI) as our physical portfolio.[1] Denote N_t as the optimal number of futures contracts to short against an existing long position in the underlying portfolio at time t. This is calculated in Equation 61.1.

e-mail: mchng@deakin.edu.au

[1] S&P Depository Receipts are yet to exist during our sample period.

$$N_t = \beta_t \times \frac{V_{CI,t}}{V_{FI,t}}$$

$$\beta_t = \frac{\sigma_{CI,FI,t}}{\sigma_{FI,t}^2} = \rho_{CI,FI,t} \times \frac{\sigma_{CI,t}}{\sigma_{FI,t}} \qquad (61.1)$$

$V_{CI,t}$ and $V_{FI,t}$ represent the value of the physical portfolio to be hedged against and the value covered by each futures contract respectively. This size-ratio $\frac{V_{CI,t}}{V_{FI,t}}$ is adjusted by β_t, which is calculated as the covariance $\sigma_{CI,FI,t}$ between the spot return $r_{CI,t}$ and futures returns $r_{FI,t}$ divided by the variance of the futures return $\sigma_{FI,t}^2$. As β_t varies during the hedging period, so does N_t, which implies a need to rebalance the hedging position. Since $\rho_{CI,FI,t} = \frac{\sigma_{CI,FI,t}}{\sigma_{CI,t} \times \sigma_{FI,t}}$, N_t can be expressed as $\rho_{CI,FI,t} \times \frac{\sigma_{CI,t}}{\sigma_{FI,t}}$, where $\sigma_{CI,t}$ is the cash index volatility. If we assume both $V_{CI,t}$ and $V_{FI,t}$ are exogenous, the OHR is the only parameter to estimate to determine the optimal N_t.[2] This demonstrates the importance of modeling $\sigma_{CI,FI,t}$ and $\sigma_{FI,t}^2$ in a dynamic hedging scheme. If we assume constant perfect positive correlation i.e. $\rho_{CI,FI,t} = 1$, modeling and forecasting the OHR is analogous to modeling and forecasting $\sigma_{CI,t}$ and $\sigma_{FI,t}$.

The preceding highlights an intimate link between the literatures on hedging and volatility modeling. Nonetheless, potential volatility transmission between spot, futures and options markets are often ignored in the OHR estimation. This is despite an incumbent literature spanning over 15 years debating the merits of implied versus historical volatility. If incremental information embedded in implied volatility exists, then incorporating such volatility transmissions should generate better volatility forecasts and improve the OHR estimation. The S&P 500 CI and FI each possesses a well-established option market. The S&P 500 futures option (FO) trading pit is located beside the futures pits on the Chicago Mercantile Exchange (CME) trading floor. The S&P 500 index option (IO) is traded on the Chicago Board Options Exchange (CBOE).

Pennings and Meulenberg [1997] provide a comprehensive review of hedging performance measures in the literature. The evaluation generally contrasts between the combined cash-futures position versus the cash position alone. Hedging performance is measured by the reduction in the variance of the combined position in Ederington [1979], the ratio of Sharpe ratios (cash-futures position divided by cash position only) in Howard and D'Antonio [1984], difference in certainty equivalent returns between the combined versus cash position in Hsin et al. [1994] and expected utility maximization in Kroner and Sultan [1993]. Hedging applications based on a bivariate GARCH framework include Baillie and Myers [1991] for US commodity futures, Kroner and Sultan [1993] for foreign

currency futures and Park and Switzer [1995] for US stock index futures. In these studies, hedging performance is based on minimizing the variance of the overall position.

Lee et al. [2000] and Yeh and Gannon [2000] evaluate out-of-sample volatility estimates generated from competing volatility models in the context of a dynamic hedging scheme. However, potential volatility transmission effects were not investigated, but transaction costs were included in the analysis in the latter paper. Chng and Gannon [2003] model contemporaneous volatility and volume effects within a framework of formalized structure of simultaneous volatility equations proposed by Gannon [1994]. The order and matrix rank conditions for the simultaneous volatility and competing misspecified volatility models are documented in this latter paper. While the resultant volatility forecasts statistically dominate those from competing volatility models, an out-of-sample evaluation based on market inference was not performed.

Au-Yeung and Gannon [2005] employ a M-GARCH model modified to allow for multiple structural breaks and volatility spillovers between the HSIF cash and index futures markets and also overnight spillovers from the S&P 500 index futures. Gannon [2005] repeated this analysis but employed a Full Information Maximum Likelihood (FIML) set of simultaneous volatility equations. Bhattacharya et al. [2007] employed the Au-Yeung and Gannon M-GARCH model to test volatility spillovers between Indian stock and share futures. Au-Yeung and Gannon [2008] repeated the early analysis of structural breaks in their M-GARCH model and showed that inclusion of volume of trade effects led to insignificant structural break parameters. Lee et al. [2009] utilize four static and a dynamic bivariate GARCH models to find the OHR for the S&P 500 and five major Asian market index futures. Lee et al. [2010] investigate hedge ratios in international futures markets in the light of the cross-country linkage and interaction using a 3SLS estimation procedure. Gannon [2010] re-visited the simultaneous volatility class of models to test transmission and spillover effects when the intra-day sampling interval reduces. In this paper further theoretical conditions for this class of models and systems Error Correction terms are defined. In all of the above estimators, hedge ratios can be extracted but no out of sample hedging performance was undertaken.

We evaluate the hedging performances of competing OHRs base on the incremental profits from interim rebalancing that each OHR generates over a static hedge. We argue that our performance measure is more consistent with the investigation on whether incorporating incremental information from implied volatility in the OHR calculation translates into incremental profits from rebalancing the futures position. We evaluate eight competing OHRs generated from competing volatility and covariance forecasts.

Our secondary objective is to model the entire time-varying variance-covariance matrix in a formal system of simultaneous volatility (SVL) equations. This can be seen as a competing estimator to variants of the restricted class of

---

[2] Strictly speaking, $V_{CI,t}$ is not entirely exogenous in that a decision is required on the proportion of the underlying asset's value to hedge against. However, this is a separate issue from the OHR determination.

bivariate GARCH estimators. However, we consider only the constant correlation bivariate GARCH and univariate GARCH estimators as similar applications in the published literature have report improved performance over regression-based estimators. The true unrestricted estimator of the simultaneous multivariate GARCH (MGARCH) hedge ratio is generated from the VEC-MGARCH form. This cannot be readily applied to model time varying covariance due to convergence problems.[3] As noted in the literature for the BEKK-GARCH and dynamic constant correlation forms of Engle [2002] and Tse and Tsui [2002], the covariance term from these models are functions of conditional standard deviations of equations in the system.

The BEKK-GARCH estimator proposed by Engle and Kroner [1995] overcomes the convergence problem by employing an estimator that guarantees a positive definite variance/covariance matrix. The base BEKK estimator is still restricted as it employs a function of the product of the respective bivariate time varying standard deviations as estimators of the time varying co-variance term. Various extensions of this class of estimator allow for functions of the standard deviations to generate the covariance term. Some in sample estimators also allow for asymmetric positive and negative return effects (sign effect) in the estimation process. One drawback with employing the asymmetric versions in out of sample forecasting applications is lack of future values of the "sign effect" to generate the forecasts.

In this paper, we utilize market data from parallel option markets to capture market anomalies, including sign effects, because these are continuously observable variables rather than discrete imposed indicator variables. This can also be seen as a benchmark for the full structural volatility system estimator that incorporates market transmission effects. It could also be seen as a benchmark for the aforementioned class of BEKK-GARCH estimators within the comparison framework of this paper and an area for future research. Clearly the real focus in this paper is to compare two alternative versions of the class of simultaneous volatility estimators SVL and ESVL. Comparisons with other estimators is restricted to those reported using similar evaluation processes.

The rest of this paper proceeds as follow. Institutional features and sampling procedures are provided in Section 61.2. In Section 61.3, competing volatility models and various methods of computing the OHR are discussed. Model estimation results are reported in Section 61.4. Section 61.5 reports the out-of-sample hedging performance. Section 61.6 concludes.

61.2 Institutional Background and Data Sampling

The analysis in our paper requires a synchronously sampled set of intraday data for all four contracts. We found it difficult to obtain a set from both options markets that was satisfactory. We decided to employ the same cash index and index futures dataset for the results reported by Miller et al. [1994]. For this dataset, a full database of both options transactions is available.[4]

The S&P 500 CI is a value-weighted broad-based market index that comprises 500 widely-held stocks.[5] It is regarded by the financial community as a barometer to gauge the performance of the US equity market. The S&P 500 FI follows a March, June, September and December contract cycle. In 1990, the contract multiplier was $500 per index point. The tick size is 0.05 point, or $25. On average, the contracts are rolled over between the 6th and 11th of the contract month. For our sample, we choose the 8th day of the delivery month as the date to switch to the next contract.

The S&P 500 FO are American options. One futures option is written on one futures contract and is quoted in index points. The tick size is 0.05.[6] These contracts follow a monthly cycle, and data is available across a range of contract months and strike prices.[7] The two nearest-to-maturity option contracts (e.g. Feb and March options written on the March futures contract) will trade at strike prices in multiples of 5. Longer maturity contracts will trade at strike prices in multiples of 10. The option is exercised at maturity if it is in the money. Both the S&P 500 FI and FO contracts are traded under the Index and Option Market Division on the CME. For each trading day, the average futures price of the front contract is used to determine the closest to money FO contract to include in our sample. The implied volatility from the FO will be the average of the implied volatility between the call and put. The S&P 500 IO contracts share similar contract specifications to

---

[3] The unrestricted vector GARCH specification seldom leads to identifiable point estimates since doing so requires the inversion of the variance-covariance matrix at each sample point. When off-diagonal covariance terms are large relative to diagonal variance terms, the determinant of the matrix tends to zero, such that the inverse matrix can be unidentified. Such cases are very likely in the context of spot and the futures returns. This technical problem is commonly addressed by imposing a constant correlation and focus on modeling time varying spot and futures volatility, which somewhat defeats the purpose of dynamic hedging.

[4] The data was supplied by TICKDATA Inc but for various reasons, they stopped collection of options data streams.

[5] Individual stock prices are multiplied by the number of shares outstanding. The products are summed up and standardized by a pre-determined base value. Base values for the index are adjusted to reflect changes in capitalization due to mergers, acquisitions and rights issues etc.

[6] However, a trade may occur at a price of 0.025 index point if it is necessary to liquidate positions to allow for both parties to trade.

[7] For the March futures contract, there are option contracts expiring at the end of Jan, Feb, March etc up to May. Options expiring prior or during the March quarterly cycle are written on the March futures contracts. Else, they are written on the June futures contract.

the FO contracts. A key difference is that the IO are cash-settled and they are European options.

From 4th Jan to 31st December 1990, we sample near-synchronous 30-min observations from the nearest-to-maturity contracts for each of the four markets. For all the markets, normal trading commences at 8.30 a.m. and finishes at 3.15 p.m. To avoid mechanically-induced opening and closing effects, we use the 8.40 a.m. and 3 p.m. prices to compute the 9 a.m. opening return and 3 p.m. closing return correspondingly.[8] When extracting implied volatilities, potential non-synchronous spot and option prices violate the specification of the Black-Scholes pricing model, which dilutes the validity of subsequent implied volatility measures. However, since both option markets are highly liquid, non-synchronicity between spot and option prices is not a major problem for our study. We calculate an option's term-to-maturity as $\frac{\text{No of trading days to maturity}}{\text{Trading days per annum}}$.[9] The continuously compounded 1-month Treasury bill rate is used to proxy the risk-free rate.[10] Lastly, the continuous-compounding annualized dividend yield daily time-series of the CI is used to back out implied volatility of the IO.

61.3 Volatility Estimators and Competing Hedge Ratios

Denote $r_{CI,t}$ and $r_{FI,t}$ as the half-hourly continuously compounded returns of CI and FI respectively. We construct CI and FI volatilities as absolute returns $\sigma_{CI,t} = |r_{CI,t}|$ and $\sigma_{FI,t} = |r_{FI,t}|$. The covariance between CI and FI is defined as $\sigma_{CI,FI,t} = |r_{CI,t}||r_{FI,t}|$.[11]

61.3.1 Constructing Out-of-Sample Hedge Ratios

To generate out-of-sample OHR forecasts, we divide our 1-year sample into two halves. The first half is our estimation sample and contains 1,613 observations. The second half,

Table 61.1 The list of competing hedge ratios

which is our test sample, contains 1,573 observations. Out-of-sample OHR projections into the test period are derived by sequentially expanding the estimation period one observation at a time to update the coefficient estimates and generate a series of one-step ahead OHR forecasts. We evaluate the hedging performance of eight hedge ratios that are constructed from different volatility sources and models. These are summarized in Table 61.1.

The first hedge ratio is obtained from a least square regression of $r_{CI,t}$ against $r_{FI,t}$ and a dummy variable Dum^{Close} for market closing effects.[12] Outlined in Equation 61.2, this β_{OLS} measure is commonly used in a static hedge, where no re-balancing occurs during the hedging period. We denote the coefficient β_{OLS} as OHR(1).

$$r_{CI,t} = \beta_0 + \beta_1(Dum^{Close}) + \beta_{OLS}(r_{FI,t}) + \varepsilon_t \quad (61.2)$$

OHR(2) is constructed from the conditional volatility of univariate GARCH(1,1) estimations for $\sigma_{CI,t}$ and $\sigma_{FI,t}$. In Equation 61.3, $\varepsilon_{CI,t}$ and $\varepsilon_{FI,t}$ are residuals obtained from the CI and FI return-equations. Lastly, $\rho_{CI,FI}$ denotes the correlation between $r_{CI,t}$ and $r_{FI,t}$.

$$\sigma^2_{CI,t+1} = \alpha_{10} + \alpha_{11}(\varepsilon^2_{CI,t}) + \beta_{11}(\sigma^2_{CI,t})$$
$$\sigma^2_{FI,t+1} = \alpha_{20} + \alpha_{21}(\varepsilon^2_{FI,t}) + \beta_{21}(\sigma^2_{FI,t})$$
$$OHR(2) = \rho_{CI,FI} \times \frac{\sigma_{CI,t+1}}{\sigma_{FI,t+1}} \quad (61.3)$$

OHR(3) is designed to be an enhanced version of OHR(2). Here, we examine the potential incremental information provided by an array of additional variables added to the CI and FI GARCH (1,1) variance equations. These include $\sigma_{FI,t}^2$ in the $\sigma_{CI,t+1}^2$ equation, $\sigma_{CI,t}^2$ in the $\sigma_{FI,t+1}^2$ equation, $\sigma_{IO,t}^2$ and $\sigma_{FO,t}^2$. In addition, we also allow potential volume effects to enter the conditional variance equations. Denote CV_{t-1} and FV_{t-1} as the corresponding change in CI and FI tick-volume.[13] Lastly, we include Dum^{Open}[14] and Dum^{Close} for market opening and closing effects. If there exists any

---

[8] For missing observations in one market, corresponding observations from other markets are excluded. This gives a total of 3,186 out of a possible 3,289 observations. There are 13 half-hourly observations per day over 253 trading days in 1990. Details of the sampling procedure can be obtained from the authors upon request.

[9] For example, an option trading on 23rd April with May as the delivery month will have 27 trading days till maturity. Following conventions, this study uses 252 days for the denominator. Thus for that option, term-to-maturity is calculated as $23/252 = 0.10714$.

[10] This is chosen over the 30 year Treasury bond rate, which may contain term structure premium.

[11] Although negative covariance is possible and should be allowed for, the spot and futures returns are expected to move in the same direction most of the time due to cost-of-carry. An examination of the data confirms this statement.

[12] $Dum^{Close} = 1$ for the 3.00 p.m. closing return, and 0 otherwise.

[13] Tick volume is defined as the number of half hourly price changes. For example, CV_t is the number of half-hourly price changes between time t-1 and t.

[14] $Dum^{Open} = 1$ for the 9.00 a.m. opening return, and 0 otherwise.

incremental information in the implied volatility and/or tick volumes that can be adequately brought out through a GARCH framework, OHR(3) should outperform OHR(2).

$$
\begin{aligned}
\sigma_{CI,t+1}^2 = {} & \alpha_{10} + \alpha_{11}(\varepsilon_{CI,t}^2) + \beta_{11}(\sigma_{CI,t}^2) + \gamma_{11}(Dum^{Open}) \\
& + \gamma_{12}(Dum^{Close}) + \gamma_{13}\sigma_{FI,t}^2 + \gamma_{14}\sigma_{IO,t}^2 \\
& + \gamma_{15}\sigma_{FO,t}^2 + \gamma_{16}(CV_t) \\
\sigma_{FI,t+1}^2 = {} & \alpha_{20} + \alpha_{21}(\varepsilon_{FI,t}^2) + \beta_{21}(\sigma_{FI,t}^2) + \gamma_{21}(Dum^{Open}) \\
& + \gamma_{22}(Dum^{Close}) + \gamma_{23}\sigma_{CI,t}^2 + \gamma_{24}\sigma_{IO,t}^2 \\
& + \gamma_{25}\sigma_{FO,t}^2 + \gamma_{26}(FV_t)
\end{aligned}
$$

$$
OHR(3) = \rho_{CI,FI} \times \frac{\sigma_{CI,t+1}}{\sigma_{FI,t+1}} \qquad (61.4)
$$

For the actual estimation, we begin with a comprehensive GARCH(1,1) specification outlined in Equation 61.4. This includes all volatility and tick-volume variables from related markets. First, we exclude non-estimable variables from the weighting series of the variance equations. Next, we use both the Wald test statistics and Akaike Information Criterion (AIC) to guide us as to which variables to exclude in an effort to systematically exclude variables from the comprehensive model. The trimmed down GARCH(1,1) specification is then used to generate out-of-sample projections for OHR(3).

Implied volatility is regarded by option traders as a forward-looking estimate. Accordingly, a hedge ratio can be constructed simply with $\sigma_{IO,t}$ and $\sigma_{FO,t}$. We term this as the implied hedge ratio (IHR), which is a novel alternative to compute hedge ratios by substituting $\sigma_{CI,t}$ with $\sigma_{IO,t}$ and $\sigma_{FI,t}$ with $\sigma_{FO,t}$. Since both $\sigma_{IO,t}$ and $\sigma_{FO,t}$ vary over time, IHR is applicable to a dynamic hedging scheme. In Equation 61.5, we label IHR as OHR(4).

$$
OHR(4) = IHR = \rho_{CI,FI} \times \left(\frac{\sigma_{IO,t}}{\sigma_{FO,t}} \right) \qquad (61.5)
$$

Since we consider only nearest to money put and call options of the front contract, and since both option markets are liquid, non-synchronicity between spot and option prices should not be a major concern. The Black-Scholes model adjusted for continuously compounded dividend yield is used to compute $\sigma_{IO,t}$ from the observed premium of the European index options, assuming dividends are non-stochastic. However, Black's (1976) model for pricing futures options cannot be readily applied to back out $\sigma_{FO,t}$, as these are American options. If the premium for early exercise is non-trivial, then this should be acknowledged.[15] However, Whaley [1986] finds that early exercise

premium exists only for in-the-money S&P 500 futures put options. Since $\sigma_{FO,t}$ is computed as the average of nearest-to-maturity call and put options, we postulate that any potential upward biases in $\sigma_{FO,t}$ from not explicitly adjusting for early exercise premium should be trivial.

OHR(5) is generated from a four-equation extended simultaneous volatility (ESVL) framework that incorporates cross-market volatility transmissions across all four S&P 500 markets. The ESVL system is based on the three-equation SVL model proposed in Gannon [1994]. Since OHR(5) requires forecasts for both $\sigma_{CI,t}$ and $\sigma_{FI,t}$, two separate ESVL systems are considered, where $\sigma_{CI,t}$ and $\sigma_{FI,t}$ is each specified as the variable to be forecasted. We refer to these as ESVL(CI) and ESVL(FI) respectively. In specifying the structure of both ESVL systems, we assume that the FO possesses the greatest informational efficiency, followed concurrently by IO and FI. The cash index ranks last in terms of efficiency ranking. This is confirmed from pairwise Granger-causality tests on the volatility time series. ESVL(CI) is presented in Equation 61.6. Diagnostic tests indicate a significant opening effect for the cash index. As such, an opening dummy Dum^{Open} is included in the estimation of ESVL(CI).

$$
\begin{aligned}
\sigma_{CI,t} = {} & \alpha_{10} + \alpha_{11}Dum^{Open} + \beta_{11}(\sigma_{FI,t}) + \beta_{12}(\sigma_{IO,t}) \\
& + \gamma_{11}(\sigma_{CI,t-1}) + \gamma_{12}(\sigma_{FI,t-1}) + \gamma_{13}(CV_{t-1}) + \varepsilon_{CI,t} \\
\sigma_{FI,t} = {} & \alpha_{20} + \alpha_{21}Dum^{Open} + \beta_{21}(\sigma_{CI,t}) + \beta_{22}(\sigma_{FO,t}) \\
& + \gamma_{21}(\sigma_{CI,t-1}) + \gamma_{22}(\sigma_{FI,t-1}) + \gamma_{23}(\sigma_{FO,t-1}) + \varepsilon_{FI,t} \\
\sigma_{IO,t} = {} & \alpha_{30} + \alpha_{31}Dum^{Open} + \beta_{31}(\sigma_{CI,t}) + \beta_{32}(\sigma_{FO,t}) \\
& + \gamma_{31}(\sigma_{CI,t-1}) + \gamma_{32}(\sigma_{IO,t-1}) + \gamma_{33}(\sigma_{FO,t-1}) + \varepsilon_{IO,t} \\
\sigma_{FO,t} = {} & \alpha_{40} + \alpha_{41}Dum^{Open} + \beta_{41}(\sigma_{CI,t}) + \beta_{42}(\sigma_{FI,t}) \\
& + \gamma_{41}(\sigma_{CI,t-1}) + \gamma_{42}(\sigma_{FI,t-1}) + \gamma_{43}(\sigma_{FO,t-1}) + \varepsilon_{FO,t}
\end{aligned}
$$
$$(61.6)$$

Since $\sigma_{CI,t}$ is the variable to be forecasted, it is present in all four equations of ESVL(CI) to ensure that a reduced-form can be obtained for generating out-of-sample forecasts. Lagged tick-volume CV_{t-1} is included in the $\sigma_{CI,t}$ equation to overcome a singularity estimation problem. The futures market leads the spot market due to lower execution costs, higher liquidity and more informed trading. As such, $\sigma_{FI,t}$ is specified to enter the $\sigma_{CI,t}$ equation. Similarly, $\sigma_{FO,t}$ is specified to enter both the $\sigma_{FI,t}$ and $\sigma_{IO,t}$ equations. $\sigma_{CI,t-1}$ and $\sigma_{FI,t-1}$ are included in the $\sigma_{IO,t}$ and $\sigma_{FO,t}$ equations to account for possible volatility feedback from the underlying assets back to the corresponding option market.

The derivation of the reduced-form ESVL(CI) is provided in the appendix. The coefficients of the reduced-form $\sigma_{CI,t}$ equation are functions of the structural coefficients from ESVL(CI). These are estimated using the estimation sample. Together with time t volatility variables, we can generate a one-step ahead forecast $\sigma_{CI,t+1}$ according to the

---

[15] While it can be shown that early exercise is never optimal for a futures option if the premium is subjected to futures-style margining, the premiums for FO are paid up front. With positive interest rates, early exercise remains a possibility.

specification of the reduced-form $\sigma_{CI,\,t}$ equation.[16] Conducting one-step ahead forecasts based on the reduced-form $\sigma_{CI,\,t}$ equation allows inherent volatility transmission effects inherent among all four S&P 500 markets to be incorporated into $\sigma_{CI,\,t+1}$. After each forecast, the coefficients are sequentially updated one observation at a time. This recursive process generates a time-series of $\sigma_{CI,\,t+1}$.[17]

ESVL(FI) is presented in Equation 61.7. A closing dummy Dum^{Close} is included as the FI market displays a significant closing effect. The series of one-step ahead forecasts $\sigma_{FI,\,t+1}$ from ESVL(FI) are obtained in a similar fashion to $\sigma_{CI,\,t+1}$. OHR(5) is presented in Equation 61.8.

$$
\begin{aligned}
\sigma_{FI,t} &= \alpha_{10} + \alpha_{11}Dum^{Close} + \beta_{11}(\sigma_{CI,t}) + \beta_{12}(\sigma_{IO,t}) \\
&\quad + \gamma_{11}(\sigma_{FI,t-1}) + \gamma_{12}(\sigma_{FO,t-1}) + \gamma_{13}(FV_{t-1}) + \varepsilon_{CI,t} \\
\sigma_{CI,t} &= \alpha_{20} + \alpha_{21}Dum^{Close} + \beta_{21}(\sigma_{FI,t}) + \beta_{22}(\sigma_{IO,t}) \\
&\quad + \gamma_{21}(\sigma_{FI,t-1}) + \gamma_{22}(\sigma_{CI,t-1}) + \gamma_{23}(\sigma_{IO,t-1}) + \varepsilon_{FI,t} \\
\sigma_{IO,t} &= \alpha_{30} + \alpha_{31}Dum^{Close} + \beta_{31}(\sigma_{FI,t}) + \beta_{32}(\sigma_{FO,t}) \\
&\quad + \gamma_{31}(\sigma_{FI,t-1}) + \gamma_{32}(\sigma_{IO,t-1}) + \gamma_{33}(\sigma_{FO,t-1}) + \varepsilon_{IO,t} \\
\sigma_{FO,t} &= \alpha_{40} + \alpha_{41}Dum^{Close} + \beta_{41}(\sigma_{FI,t}) + \beta_{42}(\sigma_{CI,t}) \\
&\quad + \gamma_{41}(\sigma_{FI,t-1}) + \gamma_{42}(\sigma_{CI,t-1}) + \gamma_{43}(\sigma_{FO,t-1}) + \varepsilon_{FO,t}
\end{aligned}
\tag{61.7}
$$

$$
OHR(5) = \rho_{CI,FI} \times \left(\frac{\sigma_{ESVL(CI),t+1}}{\sigma_{ESLV(FI),t+1}} \right)
\tag{61.8}
$$

OHR(6) is based on the modeling of a time-varying variance-covariance matrix of the spot and futures markets based on the SVL system in Equation 61.9. Two separate reduced-form equations with $\sigma_{FI,\,t}$ and $\sigma_{CI,\,FI,\,t}$ as the

variable to be forecasted are derived from (61.9). These are used to generate a series of one-step ahead forecasts for $\sigma_{FI,\,t}$ and $\sigma_{CI,\,FI,\,t}$.[18] The presence of $\sigma_{CI,\,FI,\,t}$ in the $\sigma_{FI,\,t}$ equation is driven by the fact that during non-volatile trading periods, the basis is expected to be small, reflecting cost-of-carry. But during volatile trading periods, the futures market is expected to experience a greater increase in trading activity relative to the spot market, causing a transitory deviation between the two. This implies both a decrease in $\sigma_{CI,\,FI,\,t}$ and an increase in $\sigma_{FI,\,t}$.

$$
\begin{aligned}
\sigma_{FI,t} &= \alpha_{10} + \alpha_{11}Dum^{Close} + \beta_{11}(\sigma_{CI,FI,t}) + \gamma_{11}(\sigma_{FI,t-1}) \\
&\quad + \gamma_{12}(\sigma_{CI,FI,t-1}) + \gamma_{13}(FV_{t-1}) + \varepsilon_{FI,t} \\
\sigma_{CI,t} &= \alpha_{20} + \alpha_{21}Dum^{Close} + \beta_{21}(\sigma_{FI,t}) + \gamma_{21}(\sigma_{FI,t-1}) \\
&\quad + \gamma_{22}(\sigma_{CI,t-1}) + \gamma_{23}(\sigma_{FI,CI,t-1}) + \varepsilon_{CI,t} \\
\sigma_{CI,FI,t} &= \alpha_{30} + \alpha_{31}Dum^{Close} + \beta_{31}(\sigma_{FI,t}) + \gamma_{31}(\sigma_{FI,t-1}) \\
&\quad + \gamma_{32}(\sigma_{CI,t-1}) + \gamma_{23}(\sigma_{FI,CI,t-1}) + \varepsilon_{FI,CI,t}
\end{aligned}
\tag{61.9}
$$

$$
OHR(6) = \frac{\sigma_{CI,FI,t+1}}{\sigma_{FI,t+1}^2}
\tag{61.10}
$$

As our preceding argument does not imply anything about the direction of causality, we allow $\sigma_{FI,\,t}$ to enter the $\sigma_{CI,\,FI,\,t}$ equation. OHR(6) is presented in Equation 61.10. Compared to other hedge ratios, OHR(6) does not incorporate any volatility transmissions from related options markets. However, it does consider time-varying covariance.

$$
OHR(7) = \frac{\sigma_{CI,FI,t+1}}{\sigma_{FO,t+1}^2}
\tag{61.11}
$$

$$
OHR(8) = \frac{\sigma_{CI,FI,t+1}}{\sigma_{ESVL,FI,t+1}^2}
\tag{61.12}
$$

The last two hedge ratios are based on hybrids projections from ESVL and/or SVL. Outlined in Equation 61.11, OHR (7) combines time-varying covariance forecasts generated from Equation 61.9 with potential incremental information from the implied variance of the FO market. OHR(8) is presented in Equation 61.12. Here, we combine $\sigma_{CI,\,FI,\,t}$ forecasts generated from the SVL with $\sigma_{FI,\,t}$ forecasts generated from ESVL(FI). As such, OHR(8) is the only hedge ratio in this paper that incorporates both spot-futures time-varying covariance and volatility transmission from related option markets.

---

[16] An alternative way to view the mapping of reduced form parameters back to the structural form parameters is to think about the systems in terms of the normalized matrix rank condition rather than the unnormalized matrix rank condition. In the former, there is an implied unity restriction imposed on endogenous variables in own structural equations. Then substitution between the structural and reduced forms is straightforward and in an identifiable system all structural parameters in every structural equation are identified. As such, the reduced-form equations provide unique projections of endogenous variables in the systems. However, there can be cases where alternative structural parameterizations provide non-nested competing sets of structural systems. In this case, artificial nested testing procedures need be employed to select between competing systems. In our paper, there are competing identifiable three and four equation systems. These are compared in terms of out of sample hedge ratio estimation and subsequently in terms of trade re-balancing performance.

[17] To note, utilizing ESVL-based hedge ratios may seem computationally tedious. However, as the forecasts are made one-step at a time, the majority of coefficients are stable when we sequentially expand the estimation period. Once the initial coefficient estimates are recorded, subsequent updating is computationally easy.

[18] The derivations are available upon request.

61.4   Empirical Results

61.4.1 Descriptive Statistics and Preliminary Results

In Table 61.2, descriptive statistic for $r_{CI, t}$ and $r_{FI, t}$ are presented in Panel 1, the autocorrelation of key variables in Panel 2, the correlation matrix of volatility and volume variables in Panel 3 and stationarity test statistics in Panel 4.

To note, $r_{FI, t}$ is highly significant at the 13th lag. Since our sample consists of 13 half-hourly return observations per trading day, the significant 13th lag could reflect time of the day effect that is evident in most index futures markets. The strong correlation between $\sigma_{CI, t}$ and $\sigma_{FI, t}$ is expected. Both $\sigma_{CI, t}$ and $\sigma_{FI, t}$ are also correlated with CV_t and FV_t respectively. In contrast, the correlations between $\sigma_{CI, t}$ and $\sigma_{IO, t}$ as well as between $\sigma_{FI, t}$ and $\sigma_{FO, t}$ are comparatively weaker. Lastly, $\sigma_{IO, t}$ and $\sigma_{FO, t}$ are not strongly correlated with each other, suggesting that the two option markets are not necessarily close substitutes. Augmented Dickey Fuller (ADF) test statistics indicate that cash index, futures prices and their tick volumes are integrated of order one I(1), such that $r_{CI, t}, r_{FI, t}, CV_t$ and FV_t are all stationary. The volatility time series of the four S&P markets are also tested and found to be stationary.

61.4.2 Results from Model Estimates

First, we report GARCH estimation results. Potential higher-order GARCH-effects are investigated using nested tests, but additional parameters are found to be insignificant for both $\sigma_{CI, t}$ and $\sigma_{FI, t}$. The final GARCH specification for the CI and FI are determined from a 'top-down' approach based on Wald tests statistics and the AIC to systematically exclude variables from the weighting series in the GARCH variance equation. As such, the specification of $\sigma_{CI, t}$ is slightly different from $\sigma_{FI, t}$. Both are presented below with the coefficient estimates and significance levels.

$$\sigma_{CI,t}^2 = 0.000^{a**} + 0.1065^{**}(\varepsilon_{CI,t-1}^2) + 0.7989^{**}(\sigma_{CI,t-1}^2)$$
$$+ 0.000^{**}(Dum^{Open}) + 0.0001^{**}(CV_{t-1}) + 0.0001^{**}(FV_{t-1})$$
$$\sigma_{FI,t}^2 = 0.000 + 0.0389(\varepsilon_{FI,t-1}^2) + 0.8857^{**}(\sigma_{FI,t-1}^2)$$
$$+ 0.000^{*}(Dum^{Close}) + 0.021(\sigma_{IO,t-1}^2) + 0.0001(CV_{t-1})$$
$$+ 0.0001^{**}(FV_{t-1})$$

a: * indicate significance at 5 % level; ** indicate significance at 1 % level.

Next, we discuss results from ESVL and SVL estimations. We perform two diagnostic tests to improve the validity of

Table 61.3 Log-likelihood function of the ESVL models and their augmented counterparts

	ESVL(CI) with lagged residuals	ESVL(CI)	ESVL(FI) with lagged residuals	ESVL(FI)
Log-likelihood function	2,138.01	2,094.51	1,872.68	1,647.87

Note: Strictly speaking, evaluation on improved model fitting where competingmodels are of different dimension has to be made based of other informationcriteria like the Schwartz-Bayesian Information Criteria (SBIC), or the AkaikeInformation Criterion (AIC). However, the vast improvement in parametersignificance and the removal of auto-correlation in the disturbance terms of theaugmented ESVL models are adequate justification to favor applying theaugmented versions of the ESVL models

Table 61.4 Log-likelihood of ESVL models and mis-specified-ESVL models

	ESVL (CI)	Mis-specified ESVL(CI)	ESVL (FI)	Mis-specified ESVL(FI)
Log-likelihood function	2,138.01	1,209.78	1,872.68	1,650.41

Note: Here, model evaluation can be made based solely on the log-likelihoodfunction since the corresponding competing models are of identical dimensions

the ESVL specifications. First, we test for significant autocorrelations in the residuals, which is indicative of omission of other relevant variables. Our preliminary analysis reveals significant auto-correlation in the residuals up to the second order, which generates inefficient coefficient estimates. Accordingly, the estimation of ESVL(CI) involves a two-step procedure. First, estimate ESVL(CI) according to Equation 61.6. This generates a series of residuals $u_{i,t}$ for each of the four equations. Next, include $u_{i,t-1}$ and $u_{i,t-2}$ in their corresponding equations as additional variables to proxy for other variables that are not explicitly considered. Table 61.3 reports an improvement in model fitting from an increase in the log-likelihood function.

Second, we test where the order in which volatility variables enter the various equations of the system based on our assumed informational pecking-order is appropriate. We benchmark each of the two ESVL models against two corresponding ESVL systems whether the order of efficiency is intentionally specified to be in stark contrast with ESLV(CI) and ESVL(FI). Table 61.4 reveals a huge difference in the log-likehood functions e.g. the log-likehood function for ESVL(CI) is 2,138.01, whereas for its mis-specified counterpart, the value dropped to 1,209.78. This suggests the importance of specifying the ESVL according to an appropriate order of volatility transmission.

ESVL(CI) and ESVL(FI) estimation results are reported in Tables 61.5 and 61.6 respectively. For ESVL(CI), $\sigma_{FI,t}$ is significant in the $\sigma_{CI,t}$ equation. Dum^{open} is significant in all except the $\sigma_{FO,t}$ equation. Lastly, all lag-1 volatility variables are significant in their corresponding equations.

Cross-market volatility transmission effects are more evident in ESVL(FI). Both $\sigma_{CI,t}$ and $\sigma_{FO,t}$ are significant in the $\sigma_{FI,t}$ equation. Both $\sigma_{FI,t}$ and $\sigma_{IO,t}$ are significant in the $\sigma_{CI,t}$ equation. Contemporaneous and lagged volatility from both CI and FI are significant in the $\sigma_{FO,t}$ equation. This may be indicative of volatility feedback from the underlying asset to the futures index, and then from there back to the

futures option market. Lagged residuals are all significant in their corresponding equations.

Lastly, we report SVL estimation results in Table 61.7 All own-market lag-1 volatilities are significant. All lagged residuals are significant as well. Lagged futures tick volume is also significant in the $\sigma_{FI,\,t}$ equation. To note, $\sigma_{FI,\,t}$ is significant and negative in the $\sigma_{CI,\,FI,\,t}$ equation. This result is consistent with our argument of an inverse relation between $\sigma_{FI,\,t}$ and $\sigma_{CI,\,FI,\,t}$ since the futures market experiences more trading activity than the underlying asset market in response to (say) unexpected macroeconomics news.

61.5 Out-of-Sample Hedging Performances

In this section, we evaluate the incremental profits from rebalancing the futures position that competing OHRs generate over a static hedge. Indeed, given that true volatility is unobservable, an economic evaluation in the context of an out-of-sample dynamic hedging scheme is more meaningful than a statistical evaluation. To reiterate, our focus on incremental profits from rebalancing the futures position rather than the standard risk minimization as our hedging performance criterion stems from the focus of our paper. We are interested in whether incremental information in implied volatility translates into incremental profits from rebalancing the futures position

61.5.1 Details of the Hedging Scheme

We consider hedging against the exposure of a long position in a widely-held index-tracking portfolio with short positions in index futures contracts. We refer to the combined cash and futures positions as our net position. A static hedge involves

Table 61.8 Out-of-sample incremental profits generated by competing hedge ratios

OHR ranking		Profit from Sep contract	Profit from Dec contract	Profit from both contracts	Combined cash and futures position
1st place OHR(5)	Constant covariance ESVL(CI) and ESVL(FI)	$1,591,700	$145,450	$1,737,150	$1,115,892
2nd place OHR(8)	Time varying covariance SVL, ESVL(CI) and ESVL (FI)	$1,545,225	$150,100	$1,695,325	$1,074,067

Profit/loss from the physical portfolio		$(771,716)	$150,458	$(621,258)	$(621,258)

no interim re-balancing during the hedging period. In contrast, a dynamic hedge involves interim re-balancing of the futures position during the hedging period, thereby accumulating interim profits or losses. In our dynamic hedging scheme, we consider the following scenario. An institutional trader owns a $5 million (m) widely-held equity portfolio that is very highly correlated with the S&P 500 index.[19] The objective is to protect the portfolio against market downside risk, and S&P 500 futures contracts is the only hedging instrument that will be considered.

The size of the futures position is also affected by $V_{CI,t}$ and $V_{FI,t}$. The latter is calculated as $V_{FI,t} = p_{FI,t} \times 500$ i.e. the time t futures price times the contract multiplier of $500 per index point. Note that $V_{CI,t=0} = \$5m$. Let $V_{CI,t=1} = 5m \times (1 + r_{CI,t=1})$ and $V_{CI,t=2} = V_{CI,t=1} \times (1 + r_{CI,t=2})$ etc. Accordingly, the half-hourly profit/loss from the physical portfolio at time t is $V_{CI,t} - V_{CI,t-1}$. The change in value of a futures contract at time t is $(p_{FI,t} - p_{FI,t-1}) \times 500$. Since these are short positions, a profit arises when $(p_{FI,t} - p_{FI,t-1}) < 0$. The interim profit from re-balancing the futures position at time t is calculated as $(V_{FI,t-1} - V_{FI,t}) \times (N_{t-1} - N_{t-2})$, where $(N_{t-1} - N_{t-2})$ is the 'Number of contracts rebalanced at time t − 1'.[20] To elaborate, if $(N_{t-1} - N_{t-2}) = +4$, this implies that an additional four contracts were shorted at time $t − 1$. Subsequently, if the value of the futures contract decreases between time $t − 1$ and time t e.g. $V_{FI,t-1} - V_{FI,t} = +1,000$, then the interim profit at time t generated from the rebalancing at time $t − 1$ is $4,000. If $N_{t-1} - N_{t-2} = 0$, this implies no rebalancing is required at time $t − 1$, such that the interim profit for time t is zero.

Time series plots reveal that ESVL-based OHRs exhibit more intraday variability relative to both GARCH-based OHR and IHR. Accordingly, in the hedging exercise, we allow interim rebalancing as frequently as every half-hour, which implies that rebalancing will occur more often for ESVL-based OHRs. However, this does not necessarily imply that that ESVL-based OHRs will be more profitable given the presence of transaction costs and the fact that some rebalancing transactions will generate interim losses. Intraday rebalancing does occur for certain OHRs on some days during the test period. However, consecutive half-hourly rebalancing seldom occurs. As our test sample covers the second half of 1990, we conduct our hedging exercise separately on the September and December contracts. We assume that the institutional investor rolled over from the September to December contract after the 8th trading day in September 1990, which is consistent with our sampling procedure.

61.5.2 Incremental Profit Results

The incremental profits generated by competing OHRs are reported in Table 61.8 In the September quarter of 1990, the US equity market experienced a sharp downturn. This is followed by a moderate recovery in the December quarter. The value of the physical portfolio decreased by $771,716 or 15.43 % in the September quarter. While it gained back $150,458 by the end of the December quarter, what transpired is an overall half-year loss of 12.43 % on the initial investment value of $5m. The static hedge in OHR(1), which is ranked third overall, performed surprisingly well. By construction, OHR(1) is the only hedge ratio that counterbalances any profit (loss) from the the physical portfolio. However, OHR(1) is unable to completely preserve the value of the physical portfolio, and resulted in an overall loss of $165,858. However, this is still better than having an unhedged position.

Next, the table shows that OHR(5) and OHR(8), which are generated from ESVL(CI) and ESVL(FI), clearly

---

[19] As mentioned in the introduction, we assume the S&P 500 index as our physical portfolio.

[20] Note that 'N', which represents the number of futures contracts, is always positive. The 'No. of contracts rebalanced at time t − 1' is defined as $(N_{t-1} - N_{t-2})$. As such, if $N_{t-1} = 5$ and $N_{t-2} = 3$, then the 'No. of contracts rebalanced at time t − 1' is +2, which implies shorting an additional two futures contracts.

outperform all other OHRs considered in this paper. In addition to being the only two hedge ratios that outperform the static hedge OHR(1), these ESVL-based OHRs are also the only OHRs that manage to generate sufficient profits from interim rebalancing to cover the overall loss of $621,258 incurred by the physical portfolio during the test period. The enhanced GARCH-based OHR(3) is ranked fourth overall. It performs well in that it is able to generate interim profits of $52,325 and $15,775 from both the September and December contracts, although its overall profit of $68,100 is lower than that of the static hedge. Despite incorporating additional volatility variables in the weighting series, OHR(3) is overshadowed by the ESVL-based OHRs. Similar comments apply to OHR(4) and OHR(7), the two OHRs based on implied volatilities from the IO and FO markets.

OHR(6), which focuses on modeling time-varying covariance between the spot and futures prices, performed poorly. It improves the unhedged position by a modest $20,125. The latter consists of a loss of $39,175 in the September contract and a profit of $59,300 in the December contract. To note, the gain and loss in the futures position generated by OHR(6) are in the same direction as that of the underlying portfolio. This implies that OHR(6) exacerbates the variability of the overall position, rather than reducing it. OHR(2), which is based on the standard GARCH(1,1), is ranked last. It generates losses from both contracts, with an accumulated loss of $313,050 in the futures position alone.

We draw two implications from the preceding results. First, the findings support our proposition that incorporating incremental information from implied volatilities to generate the OHR projections translates into incremental profits from interim balancing the futures position. OHRs based solely on cash-futures data or options data, have all underperform OHRs derived from a combination of cash, futures and options data, with the exception of the static hedge. The enhanced GARCH-based OHR(3) is superior to OHR(4), which is based solely on implied volatilities. It also outperforms OHR(6) and OHR(2), although OHR(3) itself failed to outperform the static hedge. Second, the profit dominance of ESVL-based OHR(5) and OHR(8) over OHR(3) suggests that the ESVL framework is more suitable than GARCH (1,1) at modeling intraday volatility transmission across the four S&P markets for the purpose of making out-of-sample OHR projections.

In general, the consideration of transaction costs offers a realistic balance of the incremental costs and benefits from interim rebalancing when bench-marked against a static hedge. However, we argue that transaction cost is a moot consideration for our paper. This is because most of the OHRs we consider, including GARCH, SVL and implied volatility, are already ranked below the static hedge OHR(1) based on gross profit. On the other hand, the ESVL-based

OHR(5) and OHR(8) do instigate very frequent re-balancing of large numbers of futures contracts throughout the test period. It is obvious that any interim rebalancing based on either OHR(5) or OHR(8) will accumulate the most transaction costs. However, note the extravagant incremental profits from OHR(5) and OHR(8) of $1,591,700 and $1,545,225 correspondingly from rebalancing the September contract, and $145,450 and $150,100 from rebalancing the December contract. For the combined September and December futures positions, each of OHR(5) and OHR(8) generated interim profits that is approximately 2.5 times the loss incurred by the physical portfolio. The presence of transaction cost is unlikely to alter the extreme dominance of the ESVL-based OHRs over the static OHR(1).

Conclusion

If option markets contribute incremental information to their underlying asset markets, then incorporating implied volatility into modeling and forecasting dynamic hedge ratios should translate into incremental profits from interim rebalancing. Our results support this proposition. In addition, we show that such cross-market volatility transmission effects are captured by a system of simultaneous volatility equations. Hedge ratios generated from extended volatility systems ESVL, which incorporate intraday volatility transmissions across all four S&P 500 cash, futures, index option and futures option markets, significantly outperform all other competing OHRs considered in this paper.

Furthermore, the ESVL-based OHRs are the only hedge ratios that manage to generate profit from rebalancing the futures positions across both the September and December contracts in excess of the losses incurred by the physical portfolio. In fact, the extravagant profit results reported in Table 61.8 should attract considerable attention not only from hedgers. Since institutional speculators do not hold the physical portfolio, their focus is solely on the profit/loss generated from actively rebalancing the futures position based on a time-varying measure of the cash-futures sensitivity. The out-of-sample OHR projections can be easily applied in a trading strategy using index futures.

61.6 Deriving the Reduced-Form of ESVL(CI)

The appendix provides details on a time-series of $\sigma_{CI, t+1}$ is generated from Equation 61.6 for constructing hedge ratios. To note, a similar methodology applies for generating a time-series of $\sigma_{FI, t+1}$. The key step involves deriving the reduced-form $\sigma_{CI, t}$ equation corresponding to Equation 61.6. We show that the reduced-form $\sigma_{CI, t}$ equation contains only

lagged volatility variables, which is required to be able to generate one-step ahead forecasts of $\sigma_{CI,\,t+1}$. The coefficients of the reduced-form $\sigma_{CI,\,t}$ are functions of coefficients from the structural system. These coefficients are derived by fitting the structural system with sample over the estimation period. These, together with time t volatility variables, allows us to obtain $\sigma_{CI,\,t+1}$. After each forecast, the estimation period is expanded by 1 observation; the coefficients are updated and $\sigma_{CI,\,t+1}$ is calculated as per normal. This recursive process generates a time-series of $\sigma_{CI,\,t+1}$. To note, while generating such hedge ratios may seem computationally tedious, but since the projections are made one-step at a time, the coefficients are stable even as we sequentially move across the test period. Thus updating the coefficient estimates is fairly easy.

The following describes the substitution process based on Equation 61.6 to obtain the reduced-form $\sigma_{CI,\,t}$. The discussion emphasizes only on the contemporaneous volatility variables. Denote the individual equations in the system below as A1, A2, A3 and A4. A1 to A7 demonstrates how we derive from the four-equation structural system to the reduced form system. The CI and FI reduced-form equations are then used to make out-of-sample volatility forecasts.

$$\sigma_{CI,t} = \alpha_{10} + \alpha_{11}Dum^{Open} + \beta_{11}(\sigma_{FI,t}) + \beta_{12}(\sigma_{IO,t})$$
$$+ \gamma_{11}(\sigma_{CI,t-1}) + \gamma_{12}(\sigma_{FI,t-1}) + \gamma_{13}(CV_{t-1}) + \varepsilon_{CI,t}$$
$$\sigma_{FI,t} = \alpha_{20} + \alpha_{21}Dum^{Open} + \beta_{21}(\sigma_{CI,t}) + \beta_{22}(\sigma_{FO,t})$$
$$+ \gamma_{21}(\sigma_{CI,t-1}) + \gamma_{22}(\sigma_{FI,t-1}) + \gamma_{23}(\sigma_{FO,t-1}) + \varepsilon_{FI,t}$$
$$\sigma_{IO,t} = \alpha_{30} + \alpha_{31}Dum^{Open} + \beta_{31}(\sigma_{CI,t}) + \beta_{32}(\sigma_{FO,t})$$
$$+ \gamma_{31}(\sigma_{CI,t-1}) + \gamma_{32}(\sigma_{IO,t-1}) + \gamma_{33}(\sigma_{FO,t-1}) + \varepsilon_{IO,t}$$
$$\sigma_{FO,t} = \alpha_{40} + \alpha_{41}Dum^{Open} + \beta_{41}(\sigma_{CI,t}) + \beta_{42}(\sigma_{FI,t})$$
$$+ \gamma_{41}(\sigma_{CI,t-1}) + \gamma_{42}(\sigma_{FI,t-1}) + \gamma_{43}(\sigma_{FO,t-1}) + \varepsilon_{FO,t}$$

First, note that the $\sigma_{FO,\,t}$ equation contains $(\sigma_{CI,\,t}, \sigma_{FI,\,t})$ and the $\sigma_{FI,\,t}$ equation contains $(\sigma_{CI,\,t}, \sigma_{FO,\,t})$. Accordingly, substituting $\sigma_{FO,\,t}$ into $\sigma_{FI,\,t}$ allows us to express $\sigma_{FI,\,t}$ in terms of $\sigma_{CI,\,t}$. Second, substitute $\sigma_{FI,\,t}$ in terms of $\sigma_{CI,\,t}$ into $\sigma_{FO,\,t}$, such that $\sigma_{FO,\,t}$ can also be expressed entirely in terms of $\sigma_{CI,\,t}$. Third, substitute $\sigma_{FO,\,t}$ in terms of $\sigma_{CI,\,t}$ into $\sigma_{IO,\,t}$, such that $\sigma_{IO,\,t}$ can also be expressed entirely in terms of $\sigma_{CI,\,t}$. Lastly, substitute $\sigma_{FI,\,t}$ and $\sigma_{IO,\,t}$ in terms of $\sigma_{CI,\,t}$ into $\sigma_{CI,\,t}$, thereby obtaining the reduced-form $\sigma_{CI,\,t}$, which is expressed entirely in terms of lagged volatility variables.

From equation A4:

$$\beta_{22}\sigma_{FO,t} = \beta_{22}\beta_{41}\sigma_{CI,t} + \beta_{22}\beta_{42}\sigma_{FI,t}$$
$$+ \beta_{22}[\alpha_{40} + \alpha_{41}Dum^{Open} + \gamma_{41}(\sigma_{CI,t-1})$$
$$+ \gamma_{42}(\sigma_{FI,t-1}) + \gamma_{43}(\sigma_{FO,t-1}) + \varepsilon_{FO,t}]$$

Substitute preceding into equation A2 and label as equation A5:

$$\sigma_{FI,t} = \alpha_{20} + \alpha_{21}Dum^{Open} + \beta_{21}(\sigma_{CI,t}) + \beta_{22}\beta_{41}\sigma_{CI,t}$$
$$+ \beta_{22}\beta_{42}\sigma_{FI,t} + \beta_{22}[\alpha_{40} + \alpha_{41}Dum^{Open} + \gamma_{41}(\sigma_{CI,t-1})$$
$$+ \gamma_{42}(\sigma_{FI,t-1}) + \gamma_{43}(\sigma_{FO,t-1}) + \varepsilon_{FO,t}]$$
$$+ \gamma_{21}(\sigma_{CI,t-1}) + \gamma_{22}(\sigma_{FI,t-1}) + \gamma_{23}(\sigma_{FO,t-1}) + \varepsilon_{FI,t}$$
$$\sigma_{FI,t} = \frac{\beta_{21} + \beta_{22}\beta_{41}}{1 - \beta_{22}\beta_{42}}\sigma_{CI,t} + \frac{1}{1 - \beta_{22}\beta_{42}}[\alpha_{20} + \alpha_{21}Dum^{Open}$$
$$+ (\gamma_{21} + \beta_{22}\gamma_{41})\sigma_{CI,t-1} + (\gamma_{22} + \beta_{22}\gamma_{41})\sigma_{FI,t-1}$$
$$+ (\gamma_{23} + \beta_{22}\gamma_{43})\sigma_{FO,t-1} + \beta_{22}\varepsilon_{FO,t} + \varepsilon_{FI,t}]$$

Substitute equation A5 into A4 and label as equation A6:

$$\sigma_{FO,t} = \beta_{41}\sigma_{CI,t} + \frac{\beta_{42}}{1 - \beta_{22}\beta_{42}}[(\beta_{21} + \beta_{22}\beta_{42})\sigma_{CI,t}$$
$$+ (\alpha_{20} + \beta_{22}\alpha_{40}) + (\alpha_{21} + \beta_{22}\alpha_{41})Dum^{Open}$$
$$+ (\gamma_{21} + \beta_{22}\gamma_{41})\sigma_{CI,t-1} + (\gamma_{22} + \beta_{22}\gamma_{42})\sigma_{FI,t-1}$$
$$+ (\gamma_{23} + \beta_{22}\gamma_{43})\sigma_{FO,t-1} + \beta_{22}\varepsilon_{FO,t} + \varepsilon_{FI,t}] + \alpha_{40}$$
$$+ \alpha_{41}Dum^{Open} + \gamma_{41}\sigma_{CI,t-1} + \gamma_{42}\sigma_{FI,t-1}$$
$$+ \gamma_{43}\sigma_{FO,t-1} + \varepsilon_{FO,t}$$
$$\sigma_{FO,t} = \frac{\beta_{41} + \beta_{21}\beta_{22}}{1 - \beta_{22}\beta_{42}}\sigma_{CI,t} + \frac{1}{1 - \beta_{22}\beta_{42}}$$
$$\times [(\alpha_{40} + \alpha_{20}\beta_{42})Dum^{Open} + (\gamma_{41} + \gamma_{21}\beta_{42})\sigma_{CI,t-1}$$
$$+ (\gamma_{42} + \gamma_{22}\beta_{42})\sigma_{FI,t-1} + (\gamma_{43} + \gamma_{23}\beta_{42})\sigma_{FO,t-1}$$
$$+ \beta_{42}\varepsilon_{FI,t} + \varepsilon_{FO,t}]$$

Substitute equation A6 into A3 and label as equation A7:

$$\sigma_{IO,t} = \beta_{31}\sigma_{CI,t} + \beta_{32}\frac{\beta_{41} + \beta_{21}\beta_{22}}{1 - \beta_{22}\beta_{42}}\sigma_{CI,t}$$
$$+ \frac{\beta_{32}}{1 - \beta_{22}\beta_{42}}[(\alpha_{40} + \alpha_{20}\beta_{42})Dum^{Open}$$
$$+ (\gamma_{41} + \gamma_{21}\beta_{42})\sigma_{CI,t-1} + (\gamma_{42} + \gamma_{22}\beta_{42})\sigma_{FI,t-1}$$
$$+ (\gamma_{43} + \gamma_{23}\beta_{42})\sigma_{FO,t-1} + \beta_{42}\varepsilon_{FI,t} + \varepsilon_{FO,t}] + \alpha_{30}$$
$$+ \alpha_{31}Dum^{Open} + \gamma_{31}(\sigma_{CI,t-1}) + \gamma_{32}(\sigma_{FI,t-1})$$
$$+ \gamma_{33}(\sigma_{FO,t-1}) + \varepsilon_{IO,t}$$
$$\sigma_{IO,t} = \frac{\beta_{31} + \beta_{32}\beta_{41} + \beta_{21}\beta_{22}\beta_{32} - \beta_{22}\beta_{31}\beta_{42}}{1 - \beta_{22}}\sigma_{CI,t}$$
$$+ \frac{1}{1 - \beta_{22}\beta_{42}}[(\beta_{30} + \beta_{40}\beta_{32} + \alpha_{20}\beta_{32}\beta_{42} - \alpha_{30}\beta_{22}\beta_{42})$$
$$+ (\alpha_{31} + \alpha_{41}\beta_{32} + \alpha_{21}\beta_{32}\beta_{42} - \gamma_{31}\beta_{22}\beta_{42})$$
$$(Dum^{Open} + \sigma_{CI,t-1})$$
$$+ (\alpha_{32} + \gamma_{42}\beta_{32} + \gamma_{22}\beta_{32}\beta_{42} - \gamma_{32}\beta_{22}\beta_{42})\sigma_{FI,t-1}$$
$$+ (\gamma_{33} + \gamma_{43}\beta_{32} + \gamma_{23}\beta_{32}\beta_{42} - \gamma_{33}\beta_{22}\beta_{42})(\sigma_{FO,t-1})$$
$$+ \beta_{32}(\varepsilon_{FO,t-1} + \beta_{42}\varepsilon_{FI-t}) + \varepsilon_{IO,t}]$$

Substitute equations A5 and A7 into A1 to obtain the reduced-form.

$$
\begin{aligned}
\sigma_{CI,t} =\ & \beta_{11}\frac{\beta_{21}+\beta_{22}\beta_{41}}{1-\beta_{22}\beta_{42}}\sigma_{CI,t} + \frac{\beta_{11}}{1-\beta_{22}\beta_{42}}\big[(\alpha_{20}+\alpha_{40}\beta_{22}) \\
& + (\alpha_{21}+\alpha_{41}\beta_{22})Dum^{Open} \\

Portfolio Insurance Strategies

Lan-chih Ho, John Cadle, and Michael Theobald

Abstract

A portfolio insurance strategy is a dynamic hedging process that provides the investor with the potential to limit downside risk while allowing participation on the upside so as to maximize the terminal value of a portfolio over a given investment horizon. This chapter firstly introduces the basic concepts and payoffs of a portfolio insurance strategy. Secondly, it describes the theory of alternative portfolio insurance strategies. Thirdly, it provides the market developments of portfolio insurance strategies and real examples of structured products. Fourthly, it addresses the implications of these strategies on the financial market stability. Finally, it empirically compares the performances of various portfolio insurance strategies during different markets and time periods.

CPPI • Expected shortfall • OBPI • Value-at-risk

62.1 Basic Concepts of Portfolio Insurance

Portfolio insurance refers to any strategy that protects the value of a portfolio of risky assets. The risky assets can be stocks, bonds, currencies, or even alternative assets, such as commodities, real assets, hedge funds, credits etc. If the value of the risky asset declines, the insurance or hedge will increase in value to help offset the decline in price of the hedged risky assets. If the price of the risky asset increases, the increase of the insured portfolio will be less than the increase in the risky asset itself but will nevertheless still increase.

Table 62.1 illustrates how portfolio insurance works. In this example, the underlying risky asset is purchased for $95 and $5 is spent on portfolio insurance. The minimum amount that the insured investor can realize is $95, but the uninsured portfolio can fall in value to a low of $75 if the market falls. If the value of the risky asset increases, the value of the insured portfolio will increase, but at a smaller rate. Figure 62.1 illustrates the profit and loss of the insured and uninsured portfolio.

Portfolio insurance allows market participants to alter the return distribution to fit investors' needs and preferences for risk. Figure 62.2 shows the effect of insurance on the expected returns of a portfolio. Notice that the uninsured portfolio has greater upside potential as well as greater downside risk, whereas the insured portfolio limits the downside loss to the cost of the hedge. The upside potential of the insured portfolio is always below that of the uninsured portfolio. The cost of the insurance is the lower return for the insured portfolio should prices increase. While some investors would prefer the greater upside potential that the uninsured portfolio offers, risk-averse investors would prefer the limited-risk characteristics that the hedged portfolio offers.

and buys the riskless asset; if the market level rises an investor switches from the riskless to the risky asset and rallies with the market. For illustrative purposes, we construct a portfolio that comprises a risky currency, the Euro (EUR), and a risk-free currency, the US dollar (USD) overnight deposit account. For comparison purposes, we assume that the initial value of EUR in the portfolio is 25%, short positions in EUR are not allowed, but that an investor can borrow via USD to buy EUR.

62.2 Theory of Alternative Portfolio Insurance Strategies

This section introduces the mechanisms behind various portfolio insurance strategies. These strategies share a common characteristic, a convex payoff function, which implies a "buy high and sell low" rule for the risky asset. If the market level declines an investor sells a fraction of the risky asset

62.2.1 Option-Based Portfolio Insurance (OBPI)

The most popular portfolio insurance strategy is the synthetic put approach of Rubinstein and Leland (1981), also referred to as an option-based portfolio insurance (OBPI)

strategy. If an investor holds a risky asset and buys one at-the-money put option on that asset, the value of the resultant portfolio will not be less than the exercise price net of the premium at expiration. Thus, the investor effectively hedges the portfolio against downside risk. However, the implied volatility is usually higher than the historical volatility in option markets, which indicates that an actual option is more expensive than a synthetic one. Therefore, a synthetic option is often used as an alternative hedging vehicle in practice.

In a currency portfolio, a synthetic put can be created by dynamically rebalancing the portfolio between the risky (foreign) and riskless (domestic) currencies according to the delta of a put option,

$$D = e^{-r_f T}[N(d_1) - 1] \quad (62.1)$$

Specifically, the investment proportion of the risky currency in the portfolio value can be expressed as:

$$W_{SynPut} = \frac{S + D * S}{V} = \frac{Se^{-r_f T}N(d_1)}{S + P} \quad (62.2)$$

where P is the premium of a European put option on foreign currency from Garman-Kohlhagen (1983),

$$P = Xe^{-rT}N(-d_2) - Se^{-r_f T}N(-d_1) \quad (62.3)$$

and $d_1 = \frac{\ln(S/X) + (r - r_f + \sigma^2/2)T}{\sigma\sqrt{T}}$ and $d_2 = d_1 - \sigma\sqrt{T}$, S is the spot exchange rate, r is the domestic risk-free interest rate, r_f is the foreign risk-free interest rate, σ is the volatility of spot exchange rate return, X is the exercise price, T is the time to expiration, and $N(*)$ is the cumulative standard normal distribution function.

Assume that the initial portfolio contains 1,000,000 units of EUR. In order to make the initial value of the EUR position in the portfolio equal to 25%, an investor needs to create a synthetic put with a delta of -0.75 and sell 750,000 units of the EUR. The dollar income ($990,075) from the EUR sold is kept in an USD cash account and earns the overnight deposit rate. Table 62.2 illustrates the adjustment process. As the EUR appreciates, the synthetic put moves less in-the-money with a delta of -0.7296 and an investor withdraws money from the USD cash account to buy more (20,407 units) EUR. On the contrary; as the EUR depreciates, the synthetic put moves further in-the-money with a delta of -0.7649 and an investor sells more (35,288 units) EUR. The daily adjustment is determined by the changes of delta.

One important parameter in the synthetic put approach is the volatility. Rendleman and O'Brien (1990), Do (2002), Do and Faff (2004), and Bertrand and Prigent (2005) use different measures of volatility, such as implied, historical and Leland's (1985) adjusted historical volatility, and discuss the effects of volatility estimation on the synthetic put strategy.

Additionally, in order to reduce transaction costs, some revisions on the rebalancing discipline are adopted, such as the time discipline with weekly/monthly rebalancing, the price discipline with adjustments according to changes in the value of the risky asset itself, or the volume discipline corresponding to changes in the number of shares that should be held. These revisions will be described in later section.

62.2.2 Constant Proportion Portfolio Insurance (CPPI)

A simplified approach, not involving complex "Greeks", is the constant proportion portfolio insurance (CPPI) strategy developed by Black and Jones (1987) and Perold (1986), and extended to fixed-income instruments by Hakanoglu, Kopprasch and Roman (1989). In CPPI, the exposure to the risky asset, E, is always kept at the cushion times a multiplier, m. The cushion, C, is the difference between the portfolio value, V, and a protected floor value, FL, and the multiplier is constant throughout the investment period:

$$E = m * C \quad (62.4)$$

$$C = V - FL \quad (62.5)$$

The investment proportion of the risky currency in the portfolio value can be expressed as:

$$W_{CPPI} = \frac{E}{V} \quad (62.6)$$

In a portfolio of securities, the floor is usually set as the discount price of a zero-coupon bond, which approaches the par value at the end of the investment horizon. In a currency portfolio, the floor is set as the forward rate, with a maturity equal to the investment horizon, that appreciates with time, that is, $F_t = F_0 * \exp(r_0 * t)$, where $F_0 = S_0 * \exp((r_0 - r_{f,0}) * T)$. Note that when the domestic risk-free rate is higher than the foreign risk-free rate, the forward rate is at a premium, which would result in short-selling of the risky asset at the beginning of the investment horizon, that is, $E = m * C = m * (V - FL) = m * Units * (S - F) < 0$. In order to make the initial value of the EUR position in the portfolio equal to 25%, a discount factor (DF) is needed, and the multiplier[1] also needs to be trimmed at the beginning of investment horizon. Thus, the synthetic floor is set as:

---

[1] The magnitude of the multiplier depends on the discount factor. The lower the discount factor, the lower the multiplier in order to keep the initial exposure fixed at 25%, i.e. $E = m * (V\text{-}FL)$.

Table 62.2 Daily adjustment process of portfolio insurance with synthetic put

Synthetic put	EURUSD S	Delta	EUR Amt sold (−)	EUR asset USD value	EUR asset %	$ Income of EUR sold	USD Cum. income	Interest income	USD asset %	Portfolio USD value	Portfolio return%
		(1)	(2)	(3)	(4) = (3)/(9)	(5)	(6) = (5) + (6) + (7)	(7)	(8) = (7)/(9)	(9) = (3) + (6)	(10) = d(9)/(9)
2007/1/1	1.3201	−0.750000	−750,000	$330,025	25.0 %	$990,075	$990,075	$145	75.0 %	$1,320,100	
2007/1/2	1.3272	−0.729593	20,407	$358,884	27.1 %	−$27,084	$963,137	$142	72.9 %	$1,322,020	0.15 %
2007/1/3	1.3170	−0.764881	−35,288	$309,651	23.5 %	$46,474	$1,009,753	$148	76.5 %	$1,319,404	−0.20 %

Table 62.3 Daily adjustment process of constant proportion portfolio insurance

				Floor discount factor (DF) = 0.94; multiplier (m) = 5.24592					
CPPI	EURUSD S	Portfolio USD value	Floor level	EUR asset USD value	EUR amount	EUR asset %	USD asset USD value	USD asset %	Portfolio return%
		(1)	(2)	(3) = ((1)–(2))*m	(4)	(5) = (3)/(1)	(6) = (1)–(3)	(7) = (6)/(1)	(8) = d(1)/(1)
2007/1/1	1.3201	$1,320,100	1.2572	$330,025	250,000	25.0%	$990,075	75.0%	
2007/1/2	1.3272	$1,322,020	1.2574	$338,752	255,238	25.6%	$963,137	74.4%	0.15%
2007/1/3	1.3170	$1,319,562	1.2577	$324,510	246,401	24.6%	$1,009,753	75.4%	−0.19%

$$F_t = DF * F_0 * \exp(r_0 * t) \qquad (62.7)$$

Table 62.3 illustrates the adjustment process. As EUR appreciates, the portfolio value increases more than the floor level increases, the cushion increases, and investors buy more (5,238 units) EUR, vice versa. There are various market developments in CPPI mechanism with additional features, such as constraints on the investment level, constraints on leverage, variable floors, and variable multipliers etc., which will be introduced in later section.

62.2.3 Risk-Based Portfolio Insurance (RBPI)

The idea of risk management has become widespread and has been applied to the asset allocation issue. By dynamically controlling for downside risk while maximizing the expected return of a portfolio, the concept of the modern risk-based asset allocation process is analogous to that of the classic portfolio insurance strategy. Zhao and Ziemba (2000) are the first to explore the portfolio payoffs between the two approaches. There are basically two popular measures of downside risk, one is the Value-at-Risk (VaR) and the other more coherent one is the Expected Shortfall (ES). Accordingly, there are two risk-based portfolio insurance (RBPI) strategies.

62.2.3.1 VaR-Based Portfolio Insurance
VaR-based portfolio insurance is a strategy that permanently controls the shortfall risk of the portfolio. The allocation to the risky asset is adjusted each day so that the shortfall probability – the probability of realizing a portfolio return (R_P) that falls below a pre-specified threshold (R) at the end of the investment period – does not exceed a target value, α (say 5%):

$$Prob(RP < -R) \leq \alpha \qquad (62.8)$$

To operationalize the shortfall risk, Herold, Maurer and Purschaker (2005) use the lower partial moment of order zero, which is equivalent to VaR, and assume a normally distributed portfolio returns:

$$LPM_0(R_P) = N\left(\frac{\tau - u}{\sigma}\right) \qquad (62.9)$$

$$R_P = W * R_A + (1 - W)^\sim * R_F \qquad (62.10)$$

where u and σ are the mean and the volatility of portfolio returns, respectively, and τ is the required portfolio return. R_A and R_F are the return of the risky and the riskless asset, respectively. Controlling for a fixed shortfall probability, the dynamic allocation process is solved for the weight of the risky asset so that the portfolio return is always higher than the required return (i.e., VaR):

$$NVaR_{\alpha,t}(R_P) = u_t(R_P) - N^{-1}(\alpha)\sigma_t(R_P) \qquad (62.11)$$

Table 62.4 illustrates the daily adjustment process. Since the VaR of a portfolio return does not change dramatically at each day during a certain period of time, the frequency of adjustment is much less than that in traditional portfolio insurance strategies. However, as EUR depreciates further, the VaR of a portfolio return increases, and the allocation to the risky asset is suggested to decrease from 25% to 24.9%, an investor sells EUR.

In comparison with the traditional portfolio insurance strategy, Herold et al. (2005) show that the VaR-based model can be regarded as a generalized version of CPPI with a dynamic and time-varying implied multiplier. The risky currency investment proportion is then given by:

$$W_{VaR} = \frac{\tau}{-Z_\alpha * \sigma} \qquad (62.12)$$

where Z_α is the α-quantile of the standard normal distribution and the process drift is assumed to be equal to zero at the daily differencing interval. The implied multiplier of the VaR model is obtained by:

$$m^{impl} = \frac{E}{C} = \frac{W * V}{\smile} = \frac{C/V}{Z_\alpha * \sigma} * \frac{V}{C} = \frac{1}{Z_\alpha * \sigma}$$
$$= \frac{1}{VaR(R_P)} \qquad (62.13)$$

where $\tau = -C/V$ is expressed in percentage terms. Thus, the inverse of the CPPI multiplier can be interpreted as the

Table 62.4 Daily adjustment process of VaR-based portfolio insurance

Control VaR	EURUSD S	Portfolio USD value	$\alpha = 5\%$ EUR Adj. rule	EUR amount	EUR asset USD value	EUR asset %	USD deposit adjust (+)	Cumulated USD amount	Interest income	USD asset %	Portfolio return%
		(1)	(2)	(3) = (2)*IniAmt	(4) = (3)*S	(5) = (4)/(1)	(6) = d(3)*S	(7) = (6) + (7) + (8)	(8)	(9) = (7)/(1)	(10) = d(1)/(1)
2007/1/1	1.3201	$1,320,100	25.0%	250,000	$330,025	25.0%		$990,075	$145.2	75.0%	
2007/1/2	1.3272	$1,322,020	25.0%	250,000	$331,800	25.1%	$0	$990,220	$146.3	74.9%	0.15%
2007/1/3	1.3170	$1,319,617	25.0%	250,000	$329,250	25.0%	$0	$990,367	$145.3	75.0%	−0.18%
2007/1/4	1.3084	$1,317,612	24.9%	249,276	$326,152	24.8%	$948	$991,459	$145.1	75.2%	−0.15%

maximum loss or worst case return that is allowed to occur over the next period. Bertrand and Prigent (2001) propose that the upper bound on the multiplier can be determined by the extreme value theory.

62.2.3.2 ES-Based Portfolio Insurance

ES-based portfolio insurance is a strategy that permanently controls the expected shortfall of the portfolio. The expected shortfall is defined as the expected value of the loss of a portfolio in a certain percentage of worst cases within a given holding period. The allocation to the risky asset is adjusted each day so that the expected shortfall does not exceed a target value.

Following the idea of Herold et al. (2005), Hamidi, Jurczenko and Maillet (2007) propose a conditional CPPI multiplier that links the traditional CPPI strategy with the RBPI strategy. The conditional CPPI multiplier is determined by keeping the risk exposure of a portfolio constant, and the risk exposure can be defined either by the VaR or by the ES:

$$m^{cond} = \frac{1}{VaR_\alpha(R_P)} \ or = \frac{1}{ES_\alpha(R_P)} \qquad (62.14)$$

By assuming a normally distributed portfolio return, the expected shortfall and the VaR are scalar multiples of the standard deviation. There will be no differences across portfolio strategies employing variance, VaR and ES risk measures. Therefore, Ho et al. (2011) use the historical distribution of portfolio returns to operate the ES-based portfolio insurance strategy:

$$HES_{\alpha,t}(R_P) = -E\big[R_P|R_P < -HVaR_{\alpha,t}(R_P)\big] \le R \quad (62.15)$$

where,

$HVaR_{\alpha,t}(R_P) = -Percentile(R_{P_{t-260}}, \ldots, R_{P_t}; \ 5\%) \le R$
among which $HVaR_{\alpha,t}(R_P)$ is the historical VaR of portfolio returns at date t at the 1-α% confidence level, $R_{P_{t-260}}, \ldots, R_{P_t}$ indicates the daily portfolio return series given a certain weight of the risky asset during the past year, and $E[*]$ is the expectation operator.

Table 62.5 illustrates the daily adjustment process. Since the ES of a portfolio return does not change dramatically at each day during a certain period of time, the frequency of adjustment is also much less than that in the traditional portfolio insurance strategies.

As mentioned at the beginning of this section, all the portfolio insurance strategies have a "buy high and sell low" rule for the risky asset. It encounters a potential limit called "cash-lock" or "cash-out". That is, if the market drops substantially an investor sells all fraction of the risky asset and locks in cash, the portfolio will never have a chance to rebound when market recovers. There are market variations to avoid this limit, which will be provided in later section.

62.3 Market Developments

In this section, the history of portfolio insurance strategy will be described, the recent market modifications in CPPI mechanisms and real examples of CPPI structured products will also be provided.

62.3.1 History of Portfolio Insurance

Derivatives markets did not exist in 1970s, asset managers were required to use dynamic asset allocation techniques such as CPPI to preserve capital. Since the beginning of 1980, significant amount of the world equity portfolio were managed in accordance to CPPI (or OBPI) until the 1987 stock market crash, where the portfolio insurance technique was blamed to be a pro-cyclical mechanism.

In 1990s, the fast expanding derivatives markets made CPPI less interesting for asset managers, and CPPI was merely used in the structured products world as a capital protection methodology for hedge funds. At the end of 1990s, there was an increased usage of CPPI for equity and fixed income portfolios. However, the burst of Internet bubble in year 2000 resulted in many CPPIs going into cash-locked.

Since 2001, low interest rate environment and high implied volatility made portfolio insurance as a methodology for providing capital protection more interesting again. CPPI re-emerged due to low structuring and trading costs. Besides, non-conventional CPPI with advantageous modifications for investors expanded.

According to Pain and Rand (2008), OBPI investments have not been popular, which reflects the difficulty in explaining options to investors. The CPPI strategy, on the other hand, is much more prevalent and stemming from a broadening in the asset classes for which investors need principal protection. Many of principal-protected structured notes are not only designed to link the performance of traditional assets, such as stocks, currencies, interest rates and bonds, but also invest in alternative risky assets, such as hedge funds, fund of hedge funds, credit derivatives, commodities, real estates, private equities, and any combination of the above assets.

Table 62.5 Daily adjustment process of ES-based portfolio insurance

			$\alpha = 5\%$

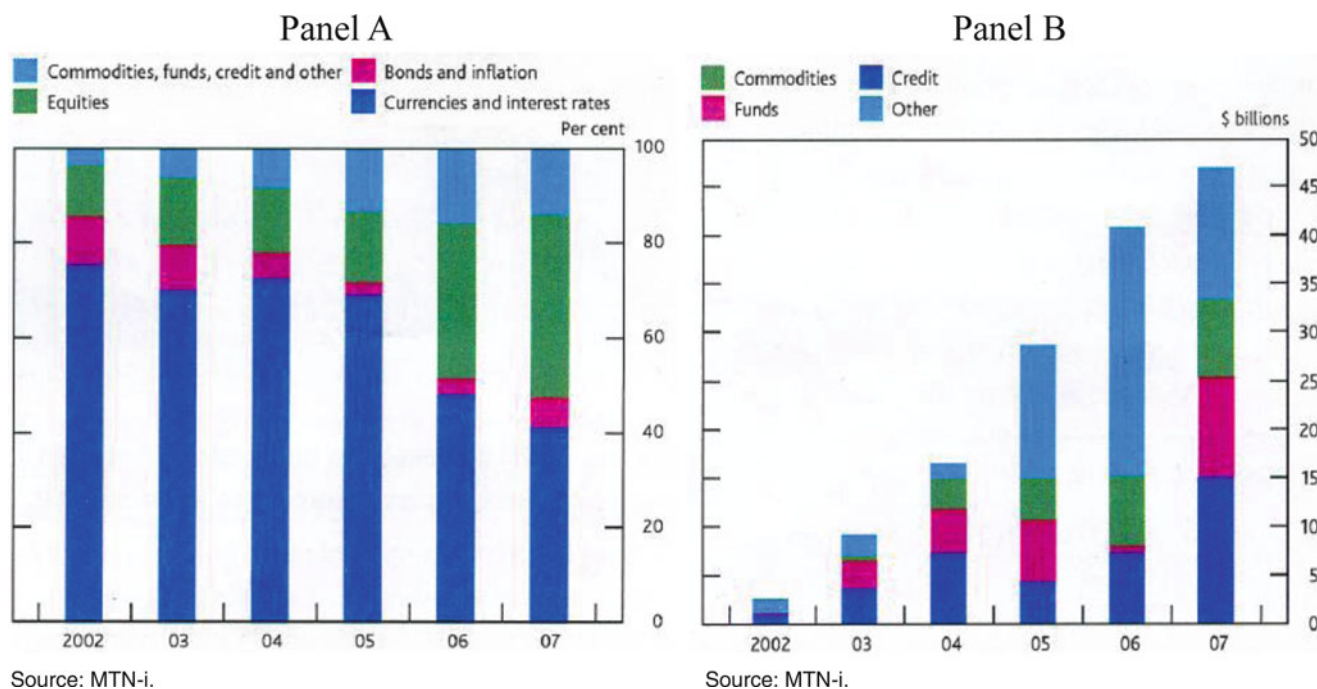

Fig. 62.3 Structured note issuance by type of risky asset

Figure 62.3 Panel A shows the evolution of shares of structured note issuance by type of risky asset. The share of notes linked to equity and alternative assets (such as commodities etc.) have increased significantly from 2002 to 2007. In 2007, the shares of currencies and equities are both around 40%, alternative assets occupy more than 10% and bonds have the least share. Figure 62.3 Panel B further illustrates the evolution of issuance of structured notes linked to alternative assets. The total issuance has grown five times, from around US$ 5 billion in 2002 to over US$ 45 billion in 2007.

As for market participants, according to Pain and Rand (2008), portfolio insurance products are more prevalent in Europe than in the United States. The key issuers (sellers) are typically large investment banks that can provide the necessary structuring and marketing expertise. The main investors include both institutional and retail clients, such as pension funds, insurance companies, private banks who purchase products for onward sale to their clients, and high net wealth individuals. Among which, the institutional investors are especially important in continental Europe.

62.3.2 Recent Modifications in CPPI Mechanisms

Since the re-emergence of portfolio insurance strategies, CPPI investments have evolved to incorporate various different features. Of particular importance are the key components in the design of CPPI investments, i.e., the floor, the multiplier, and the exposure to risky assets.

62.3.2.1 Modifications in Floor

Ratchet floor: The performance of CPPI investments is price dependent, any gains at a particular point in time may still be lost if the underlying asset price subsequently falls. To address this, products with a "ratchet" mechanism have been introduced to lock in a proportion of upside performance. More specifically, the floor can be set as a percentage of the historical maximum net asset value of the portfolio. That is, the floor jumps up with the portfolio value in order to reduce the risky asset allocation when the market peaks. The time-invariant portfolio protection (TIPP) strategy proposed by Estep and Kritzman (1988) reflects this variation.

Margin floor: The converse to the above case is when the market falls substantially for the cushion to approach zero, the exposure to the risky asset also approaches zero. Under a conventional CPPI, this leads to "cash-out" where the portfolio is fully invested in the risk-free asset, with no possibility of regaining any exposure. One method to counter this is to adjust the starting floor value, by augmenting this by a margin, which can later be used to help regain some exposure after a near cash-out situation. This feature is included in the Structured Note Example (1) below.

Straight-line floor: The floor in a conventional CPPI is a zero-coupon bond, which is sensitive to the level of interest rates. When interest rates fall, the floor would rise and the allocation switches away from the risky asset. This in turn would limit the subsequent potential upside from the CPPI. However, this sensitivity can be removed by allowing the

floor to vary linearly with time. The Structured Note Example (3) contains this feature.

62.3.2.2 Modifications in Multiplier

Rather than having a constant multiplier in a conventional CPPI, dynamic portfolio insurance (DPI) allows for the multiplier to vary over time in relation to the volatility of the risky asset and reflects investors' appetite for risk. In fact, DPI is a cushion management technique that quantifies the level of risk born by the investment in the risky asset. There is often a maximum level for the multiplier, which can be determined by stress testing on the returns of the risky asset using extreme value theory (EVT). The risk-based portfolio insurance strategies in the earlier section reflect this feature.

62.3.2.3 Modifications in the Exposure to Risky Assets

Constraints on the investment level: Another method to avoid the "cash-out" situation when a market falls is to incorporate a minimum level of investment in the risky asset. On the contrary, to avoid unbounded investment in the risky asset as a market rallies, a maximum investment level can also be imposed. This feature can be found in Examples (1), (3) and (4).

Constraints on leverage: Exposure to the risky asset of more than the initial available funds can be achieved by allowing borrowing. There may be constraints on how much can be borrowed. This feature is incorporated in Examples (1) and (4).

Volatility Caps: Some CPPI products include mechanisms that allow the percentage exposure to the risky asset to be reduced if its realized volatility exceeds a certain level. This feature is embedded in Example (2), when realized volatility is greater than the implied volatility, which leads to the value of Reserve Account smaller than 4.5%, the Note stops investing in the Risky Asset and switches into zero coupon bond.

62.3.3 Examples of CPPI Structured Products

Many of the issuances of principal-protected products are designed as medium-term structured notes or deposits, with maturities ranging from 5 to 15 years. The model offers the flexibility to build in additional features, such as zero-coupon, fixed or contingent coupons, and any variations mentioned above. Table 62.6 lists some real examples of CPPI structured products.

62.4 Implications for Financial Market Stability

62.4.1 Amplification of Market Price Movements

The portfolio insurance strategies mentioned in this chapter share a common "buy high and sell low" rule for the risky asset. When the underlying asset markets move in one particular direction, either trending up or down, these actions could conceivably have feedback effects in markets that amplify price developments. If the underlying asset markets are deep and liquid, the feedback effects may be limited. However, if the underlying asset markets are less liquid (for example, CPPI products linked to hedge funds on credit derivatives), even small actions may reinforce market prices. Moreover, some underlying assets that appear less correlated in normal conditions may become more correlated in stress situations when CPPI products all look to reduce risky positions simultaneously. Taken together the stress situations together with the inherently less liquid nature of certain underlying asset markets, the feedback impacts would be large.

Duarte (2008) shows that not only the risky asset prices are amplified, the dynamic hedging strategy adopted by MBS portfolio managers is analogous to a CPPI mechanism, which also intensifies the price movements of riskless assets such as Treasury Notes. Suppose, for example, that an MBS portfolio manager hedges the portfolio duration risk with a short position in Treasury Notes. If interest rates drop, the MBS portfolio duration decreases due to a higher probability of refinancing. As a result, the manager will have a portfolio with negative duration. To adjust portfolio duration back to zero, the manager must buy Treasury Notes. If, on the other hand, interest rates increase, the MBS portfolio duration increases and the manager must short additional Treasury Notes. In other words, the dynamic hedging strategy for MBS portfolio makes the manager buy Treasury Notes when prices are going up and sell Treasury Notes when prices are going down. This hedging behavior has the effect of reinforcing both the movement of Treasury Notes prices and their volatility. Table 62.7 shows some statistics on mortgage-related and Treasury securities. Since year 2000, the outstanding amount of residential mortgage-related security becomes larger than that of Treasury Debt. Provided that bond prices are affected by flows in the Treasury market, the huge MBS hedging flows will have a big impact on the riskless bond prices.

Table 62.6 Examples of CPPI structured products

Product	(1) Lehman brothers best profile SPA note
Protection	100% at maturity
Currency/tenor	USD/7 years
Participation Rate (PR)	50%
Each year end coupon (Cpn_N)	At the end of year 1–6, the Note may pay a coupon with an amount as $Cpn\_N = PR^* Max[0\%; Max(BA1\_N, BA2\_N, BA3\_N) - 100\%]$ Where BAi_N is the value of the ith Balanced Account at the end of the Nth year After coupon payment, each of the 3 BAi will be adjusted by deducting the coupon amount for the relevant year
Redemption Amount (RA)	At maturity, the Note will redeem with an amount calculated as $RA = Max[100\%; Max(BA1\_F, BA2\_F, BA3\_F)]$ Where BAi_F is the value of the ith Balanced Account at maturity

Bond floor	Zero Coupon Bond: Initial Level [37%]
Multiplier	6.67x
Exposure to risky assets	Initial [63%] Min Exposure [20%], Max Exposure [200%]; Max Leverage [100%]

Fortunately, according to Pain and Rand (2008), market contacts reveal that the amount of portfolio insurance-related dynamic hedging flows still remain modest relative to the size of the corresponding underlying asset markets, even in those new asset classes. Moreover, market contacts do not perceive portfolio insurance as a significant factor during the 2007 financial market turmoil as that perceived as the driving force during the 1987 stock market crash.

62.4.2 Gap Risk

The biggest potential risk of implementing a portfolio insurance strategy is that the payoffs are particularly vulnerable to sudden huge drops in the risky asset prices before the portfolio can be rebalanced. In such cases, the value of the insured portfolio would fall below the floor; however, a hard guarantee, such as 100% principal protection, to the

Table 62.7 Statistics on mortgage-related and treasury securities

	1995	1999	2000	2001	2002	2003
	Outstanding residential mortgage-related security					
Agency MBSs	1,554	2,252	2,439	2,770	3,089	3,364
Nonagency MBSs	224	455	500	591	692	843
Total	1,779	2,707	2,939	3,362	3,781	4,207
	Outstanding US treasury debt					
Bills	761	737	647	811	889	929
Notes/bonds	2,531	2,429	2,184	2,017	2,170	2,470
Total	3,292	3,166	2,831	2,828	3,059	3,399

investors must be fulfilled at the end of investment horizon. Therefore, the issuers of CPPI products would suffer a gap risk. In particular, if the issuers issue several CPPI products written on different underlying assets, and those seemingly uncorrelated assets suddenly become much more correlated in stressed conditions (such as the credit crunch led by subprime mortgage crisis since September 2007), then the scale of the gap risk may be very much underestimated. The unexpected huge losses may jeopardize the issuers and the stability of financial markets.

Figure 62.4 shows two of the simulated outcomes of Example (3). Assume that the price of the underlying risky asset follows a geometric Brownian Motion with a drift of 7% (p.a.) and a volatility term. When the volatility increases from 0% to 30%, the reference portfolio value would fall below the bond floor; however, a 100% principal protection to the investors must be fulfilled at the end of investment horizon. Therefore, the issuers would suffer a gap risk.

In theory, the issuer of CPPI products can hedge such exposure to gap risk by options. The issuer needs to model the likely worst-case move in the risky asset price before the
Fig. 62.4 Simulated performances of structured note example (3)

next rebalancing opportunity and build the cost of this implicit option into the premiums and fees charged to the investors or provided by capital. But, in practice, the pricing of such options can be quite complex, because the issuer does not exactly know the underlying asset price processes and their correlations in stressed markets. Furthermore, it is difficult for the issuers to find available options through which to hedge their exposures.

Pain and Rand (2008) report that some issuers of CPPI products create securities that package up the gap risk and sell these to investors, including private banks and funds. But these structured derivatives are not popular due to the complicated nature of risk. Other issuers seek to limit their exposure to gap risk by other imprecise hedging vehicles or so-called proxy hedging. But, this in turn exposes the issuers to the basis risk.

62.5 Empirical Comparison of Alternative Portfolio Insurance Strategies

In the late 1980s and early 1990s, much of the research in this area focused on simulated comparisons of the performances among alternative portfolio insurance strategies. In the 2000s, most studies use empirical data to analyze the circumstances where one strategy would outperform the others based on some modifications on certain portfolio insurance mechanisms, such as volatility input, rebalancing intervals etc. The performances are typically evaluated by floor protection – whether they achieve the desired floor at the end of the investment horizon, the cost of insurance – the opportunity cost of forfeiting upward markets, and the Sharpe ratio. Listed below are some of the studies that have appeared in academic journals.

62.5.1 Zhu and Kavee (1988)

They evaluate and compare the performances of the two traditional portfolio strategies, the synthetic put approach of Rubinstein and Leland (1981) and the constant proportion approach of Black and Jones (1987). They employ a Monte Carlo simulation methodology, assuming log normally distributed daily returns with an annual mean return of 15% and paired with different values for market volatility, in order to discover whether these strategies can really guarantee the floor return and how much investors have to pay for the protection.

Both strategies are able to reshape the return distribution so as to reduce downside risk and retain a certain part of the upside gains. However, they demonstrate that a certain degree of protection can be achieved at a considerable cost. There are two types of costs in implementing a portfolio

insurance strategy. The first is the explicit cost, that is, the transactions costs. The other is the implicit cost, which is the average return forgone in exchange for protection against the downside risk. When the market becomes volatile, the protection error of the synthetic put approach increases, and the transaction costs may be unbearable. On the contrary, while the constant proportion approach may have lower transactions costs, its implicit cost may still be substantial.

62.5.2 Perold and Sharpe (1988)

Using simulated stocks and bills prices, they examine and compare how the four dynamic asset allocation strategies, namely, the buy-and-hold, constant mix, CPPI and OBPI, perform in bull, bear and flat markets and in volatile and not-so-volatile markets.

CPPI and OBPI strategies sell stocks as the market falls and buy stocks as the market rises. This dynamic allocation rule represents the purchase of portfolio insurance and has a convex payoff function, which results in a better downside protection and a better upside potential than a buy-and-hold strategy. However, they do worse in relatively trendless, volatile markets.

On the contrary, a constant mix strategy – holding a constant fraction of wealth in stocks – buys stocks as the market falls and sells them as it rises. This rebalancing rule effectively represents the sale of portfolio insurance and has a concave payoff function, which leads to less downside protection than, and not as much upside as, a buy-and-hold strategy. However, it does best in relatively trendless and volatile markets.

They suggest that no one particular type of dynamic strategy is best in all situations. Financial analysts can help investors understand the implications of various strategies, but they cannot, and should not, choose a strategy without a substantial understanding of an investor's circumstances and desires.

62.5.3 Rendleman and O'Brien (1990)

They address the issue that the mis-estimation of volatility input can have a significant impact on the final payoffs of a portfolio using a synthetic put strategy. In an OBPI strategy, the daily portfolio adjustments depend on the delta of the put option on the risky asset. In the original Black and Scholes (1973) valuation equation, the delta at each day is a function of the following variables:

$$D_t = f(S_t, \ \bar{k}_0, \ \bar{r}_0, \ \sigma_0, \ T) \qquad (62.16)$$

where S_t is the price of the risky asset at date t, k_0 the strike price, r_0 the annual continuously compounded riskless rate of interest, σ_0 the ex-ante volatility parameter at the beginning of the insurance period, and T the maturity of the option.

Assume that at the beginning of the insurance period, one manager predicts a high-volatile market and a 20% annualized volatility, while a second manager believes a low-volatile market and a 10% volatility. The delta for the first manager is higher which means he would buy more insurance and allocate less to a position in the risky asset. Assume that the ex-post volatility turns out to be 10%. The second manager will have made the proper allocation between risky and riskless assets. In contrast, the high-estimate manager will have invested too little in the risky asset. This misallocation would lose the opportunity of participating in the price appreciation in a strong market. Thus, a manager who underestimates volatility will typically end up buying less insurance than is necessary to ensure a given return, while a manager who overestimates volatility will buy more insurance than is necessary and forgo gains.

As for the issue of portfolio rebalancing, they examine adjustment frequencies by time intervals, namely, daily, weekly, monthly and bi-monthly. The effect (error) is measured as the difference of the horizon insurance values between non-continuous and continuous trading. They suggest that weekly rebalancing produces an amount of error that appears to be tolerable by most portfolio managers.

More importantly, they address the biggest potential risk of implementing portfolio insurance strategies – the gap risk, by simulating the performance of the OBPI strategy over the period of the October 1987 market crash. They indicate that most insured portfolios would have fallen short of their promised values because the managers would not be able to adjust the portfolio in time before a big drop in the market. The gap risk will be discussed further in the financial stability section.

62.5.4 Loria, Pham and Sim (1991)

They simulate the performance of a synthetic put strategy using futures contracts based on the Australian All Ordinaries Index for the period from April 1984 to March 1989. Their study contains 20 consecutive non-overlapping 3-month insurance periods whose expiration dates coincide with the expiration dates of each SPI futures contract traded on the Sydney Futures Exchange. Four implementation scenarios are examined: a zero floor versus five percent floor which correspond to a portfolio return of 0% and −5% per annual, respectively; and a realized volatility versus Leland's (1985) modified volatility. They report that there is no perfect guarantee of loss prevention under any scenario. Even in the scenario with a 5% floor and modified

volatility, two out of 20 contracts do not meet the desired floor. In addition, the OBPI strategy is most effective under severe market under severe market conditions. In other periods characterized by insignificant market declines, the value of the insured portfolio is below that of the market portfolio. They suggest futures mispricing may be one potential culprit for this outcome.

62.5.5 Do and Faff (2004)

This empirical paper is an extension of Loria et al. (1991). They examine two approaches (the OBPI and CPPI) and conduct simulations across two implementation strategies (via Australia stock index and bills, and via SPI futures and stock index). Furthermore, they consider the use of implied volatility as an input into the model, and the use of a zero floor versus five percent floor. The dataset consists of 59 non-overlapping 3-month insurance periods, which span from October 1987 to December 2002. Thus, their key contributions relative to Loria et al. (1991) are the examination of a futures-based CPPI, a fine-tuned algorithm that allows for dividend payments, the consideration of ex ante volatility information, and more up to date data.

In terms of floor protection, the futures-based portfolio insurance implementation generally dominates its index-and-bill rival in both floor specifications, which reflects the low transaction costs in the futures market. Furthermore, the perfect floor protection is possible when implied volatility is used rather than using ex-post volatilities. From the cost of insurance perspective, the futures-based strategy generally induces a lower cost of insurance than its index-and-bill rival in both floor specifications, which reflects the same reason as above. However, the cost of insurance is higher when implied volatility is used compared to ex-post volatilities. The possible explanation is that the implied volatility is often higher than the same period ex-post volatility, which results in over-hedging. As for the performances between the OBPI and CPPI approaches, there is no strong evidence to distinguish between them. Within the futures-based implementation, the synthetic put appears to dominate the CPPI with respect to floor protection, while the latter appears to slightly outperform in terms of upside participation.

They also examine whether portfolio insurance strategies work under stress conditions by assessing the strategies' effectiveness during tranquil and turbulent periods. Tranquil periods are defined as ones that return more than −4% and have a realized volatility of less than 15%; violation of either one or both of these conditions is regarded as indicating a turbulent period. All portfolio insurance strategies achieve 100% floor protection during tranquil periods whereas the futures-based OBPI approach records the highest portfolio

return. During turbulent times, futures-based portfolio insurance continues to perform quite well. The 1987 stock market crash makes the assessment difficult because of trading halts. However, assuming the futures continued to trade during that crisis, from the algorithm's perspective, the futures-based CPPI maintains a positive return, while the OBPI results in a negative return.

62.5.6 Cesari and Cremonini (2003)

This study is an extensive comparison of a wide variety of traditional portfolio insurance strategies. There are basically five dynamic asset allocation strategies: (1) buy-and-hold (BH), (2) constant mix (CM), (3) constant proportion (without and with the lock-in of profits, CP and CPL), (4) the option-based approach (with three variations, BCDT, NL, PS), and (5) technical strategy (with two kinds of stop-loss mechanism, MA and MA2), therefore, nine strategies in total are considered.

For each strategy, eight measures for risk, return and risk-adjusted performance are calculated, namely, mean return, standard deviation, asymmetry, kurtosis, downside deviation, Sharpe ratio, Sortino ratio and return at risk. The strategies are then compared in different market situations (bear, no-trend, bull markets) and with different market volatility periods (low, medium and high periods), taking into account transaction costs and discrete rebalancing of portfolios. The three market situations are defined accordingly if market average returns fall into the three ranges: $(-30\%, -5\%)$, $(-5\%, +5\%)$, $(+5\%, +30\%)$, and the three ranges for the volatile periods are: $(10\%, 15\%)$, $(15\%, 25\%)$, $(25\%, 30\%)$. Transaction costs are treated in two ways: a proportional cost to the value traded, and a correction to the Leland's (1985) option volatility. Two main rebalancing disciplines are used: a time discipline with weekly adjustment, and a price discipline with adjustment only when prices are increased/decreased by 2.5% with respect to the previous rebalance time.

Monte Carlo simulations of MSCI World, North America, Europe and Pacific stock market returns show that no strategy is dominant in all market situations. However, in bear and no-trend markets, CP and CPL strategies appear to be the best choice. In a bull market or in no-trend but with high volatility market, the CM strategy is preferable. If the market phase is unknown, CP, CPL and BCDT strategies are recommended. In addition, these results are independent of the volatility level and the risk-adjusted performance measure adopted.

62.5.7 Herold, Maurer and Purschaker (2005)

By constructing a fixed income portfolio, in which the risky asset is the JPMorgan government bond index and the riskless asset is cash (1-month yield), they compare the hedging performances between the traditional CPPI strategy and the risk-based (specifically, VaR-based) strategy with a 1 year investment horizon that begins at each year from 1987 to 2003. CPPI avoids losses in the bear years of 1994 and 1999. The mean return is inferior to (about 40 bp below) that of the risk-based strategy. CPPI also produces a higher turnover.

62.5.8 Hamidi, Jurczenko and Maillet (2009)

Although they propose a conditional CPPI multiplier determined either by VaR or by ES, only a VaR-based measure is studied in this empirical work, and the ES measure is absent for future research.

The data set contains 29 years of daily returns of the Dow Jones Index, from 2 January 1987 to 20 May 2005, 4641 observations in total. They use a rolling window of 3,033 returns to estimate the VaR, and there are 1,608 VaRs in the out-of-sample period. They resort to eight methods of VaR calculation: one non-parametric method using the historical simulation approach; three parametric methods based on distributional assumptions, namely, the normal VaR, the RiskMetrics VaR based on the normal distribution, and the GARCH VaR based on the Student-t distribution; four semi-parametric methods using quantile regression to estimate the conditional autoregressive VaR (CAViaR), namely, the symmetric Absolute Value CAViaR, the Asymmetric Slope CAViaR, the IGARCH(1,1) CAViaR, and the Adaptive CAViaR.

According to the 1,608 back-testing results, the Asymmetric Slope CAViaR is the best model to fit the data. After having calculated the VaR values, the conditional multipliers can be determined. The estimations spread between 1.5 and 6, which are compatible with multiple values used by practitioners in the market (between 3 and 8).

Using the time-varying CPPI multipliers estimated by different methods, and a "multi-start" analysis – the fixed 1-year investment horizon beginning at every day of the out-of-sample period, they find that the final returns of these insured portfolios are not significantly different.

62.5.9 Ho, Cadle and Theobald (2011)

This empirical study presents a complete structure of comparing traditional portfolio insurance strategies (OBPI, CPPI) with modern risk-based portfolio insurance strategies (VaR-, ES-based RBPI). By constructing a currency portfolio, in which the risky asset is the Australian dollar and the riskless asset is a U.S. dollar overnight deposit, they compare the dynamic hedging performances between the traditional and the modern strategies with a 1-year investment horizon that begins at each year from 2001 to 2007.

When implementing the OBPI strategy, the delta is calculated based on the modified Black-Scholes formula,

$D_t = f(S_t, \bar{k}_0, r_t, \sigma_t, T)$. That is, daily annualized historical volatilities are used as inputs in the put-replication process instead of the constant ex-ante or the implied volatility in the original model to mitigate the volatility misestimation problem. Besides, the latter two parameters would make the portfolio daily returns more volatile. The interest rates are also updated daily for the same reason. When CPPI is implemented, the possible upper bounds of the multiplier are examined via the extreme value theory, which ranges from 4 to 6 corresponding to different confidence levels. When risk-based approaches are employed, both a historical distribution and a normal distribution with exponentially weighted volatility of risky asset returns are assumed. A daily rebalancing principle is adopted in their research without any modification to show the original results of hedging.

The performances are evaluated from six differing perspectives. In terms of the Sharpe ratio and the volatility of portfolio returns, the CPPI is the best performer, while the VaR based upon the normal distribution is the worst. From the perspective that the return distribution of the hedged portfolio is shifted to the right and in terms of both the average and the cumulative portfolio returns across years, the ES-based strategy using the historical distribution ranks first. Moreover, the ES-based strategy results in a lower turnover within the investment horizon, thereby saving transaction costs.

Conclusion

A portfolio insurance strategy is a dynamic hedging process that provides the investor with the potential to limit downside risk while allowing participation on the upside so as to maximize the terminal value of a portfolio over a given investment horizon. This paper looks at the basic concept of portfolio insurance, the alternative dynamic hedging strategies available to the portfolio manager, the recent market developments on the principal-protected structured products, the implications of portfolio insurance on financial market stability, and finally, the empirical comparison of the performances of various portfolio insurance strategies.

Abstract

This article reviews the methodologies of testing asset pricing models which are dominantly used in the literature; time-series regression tests and cross-sectional regression tests. We provide some explanations for the test procedure of time-series regression tests and cross-sectional regression tests. We discuss individual t-test, the joint F-test by Gibbons, Ross, and Shanken (Econometrica 57:1121–1152, 1989) and tests based on the generalized method of moments estimation. We also explain the two-pass test methodology and discuss the errors-in-variables problem which occurs inevitably in the two-pass methodology.

Keywords

Asset pricing models • Cross-sectional tests • Time-series tests

63.1   Introduction

It is very important to determine an appropriate asset pricing model since it is essential in estimating cost of capital for firms and discount rates for project cash flows and evaluating the performance of managed portfolios, etc. Since Sharpe (1964) proposed Capital Asset Pricing Model (CAPM), many theoretical and empirical asset pricing models have been suggested in the literature. In particular, numerous empirical asset pricing models have been suggested with some arguments. It is important, therefore, to determine an asset pricing model among these that describes well the intertemporal and cross-sectional dynamics of asset returns. To do so, it is essential to apply a correct test procedure.

This article reviews the methodologies of testing asset pricing models (see also Kim 2011). We provide some

explanations for two testing methodologies dominantly used in the literature; time-series regression tests and cross-sectional regression tests. Time-series tests focus on the intertemporal explanatory power of returns on given factors for returns on test assets returns and on the pricing error of the given asset pricing model. Meanwhile, the cross-sectional tests focus on the explanatory power of factor loadings for asset returns in the cross-section. We explain individual t-test and the joint F-test by Gibbons, Ross, and Shanken (1989) which are used in time-series tests. We also explain the two-pass test methodology that is used in cross-sectional test, and discuss the errors-in-variables problem which occurs inevitably in the two-pass methodology. Moreover, we provide some explanations of tests based on the generalized method of moments estimation and tests based on the Hansen-Jagannathan (1997) distance.

This article is organized as follows. Section 63.2 explains time-series regression tests, Section 63.3 discuss tests based on the generalized method of moments estimation, and Section 63.4 explains cross-sectional regression tests and discusses the errors-in-variables problem. Section 63.5 concludes.

63.2 Time-Series Tests

63.2.1 The Factor Model

Consider the following return generating process of the N assets. The returns of an asset i are generated by the following linear equation

$$R_{it} - R_{ft} = \alpha_i + \beta_i' F_t + \varepsilon_{it}, \qquad (63.1)$$

where R_{it} is the return on the asset i ($i = 1, \cdots, N$) at time t ($t = 1, \cdots, T$), R_{ft} is the risk-free return, ε_{it} is the residual or idiosyncratic return with mean zero and covariance matrix Σ_ε, β_i is a ($K \times 1$) vector of the factor loadings, and F_t is a ($K \times 1$) vector of the factor portfolio returns. If the model (63.1) is well-specified, the equilibrium pricing equation is described as

$$E(r_{i,t}) = \gamma' \beta_i \qquad (63.2)$$

where γ is a ($K \times 1$) risk premia vector (the j-th element γ_j is the risk premium of the j-th risk factor), $r_{i,t}$ is the return of asset i in excess of the riskless rate of return ($= R_{it} - R_{ft}$). The above pricing equation of (63.2) has one restriction that the intercepts should be zero. The intercept from the time-series factor model of Equation 63.1 is interpreted as the pricing error. It is also dubbed the Jensen alpha. Thus, if $\alpha_i = 0$ for all test assets, we interpret this as evidence that supports the validity of a given factor model or the mean-variance efficiency of a given portfolio (or a linear combination of given factor portfolios).

63.2.2 Individual t-Test

The typical examples of time-series tests using Equation 63.1 are Black, Jensen and Scholes (1972) (hereafter BJS) and Fama and French (1993). BJS estimate the time-series regression model of Equation 63.1 for each of test assets and examine whether the intercept estimate α_i is significantly different from zero to test the validity of the CAPM. They use ten beta-sorted portfolios as test assets. Fama and French (1993) also estimate Equation 63.1 with three stock factor portfolios and two bond market portfolios by using 25 size-BM sorted portfolios as test assets. These two studies and many other studies use individual t-statistic of the intercept estimates to test the validity of a given factor model.

63.2.3 Joint F-Test

To test whether the intercept estimates of the time-series regression 63.1 are jointly different from zero, Gibbons, Ross, and Shanken (1989) (hereafter GRS) develop an F-tests. If the given asset pricing model or factor model is well-specified, the intercept estimates should not be different from zero. Therefore GRS F-statistic is to test a joint hypothesis $H_0 : \alpha = (\alpha_1, \alpha_2, \cdots, \alpha_N)' = 0$. Since the null hypothesis indicates that some linear combination of the factor portfolios is on the mean-variance efficiency boundary, the GRS test is in fact to test whether the linear combination of the factor portfolios is on the mean-variance efficient boundary.

Assuming the error terms are jointly normally distributed with mean zero and nonsingular error covariance matrix Σ_ε, GRS suggest the following test statistic for the null hypothesis:

$$W = \left[\frac{T(T-N-K)}{N(T-K-1)} \right] \left[\frac{\widehat{\alpha}' \widehat{\sum}_\varepsilon^{-1} \widehat{\alpha}}{1 + \hat{\vartheta}^2} \right]$$
$$\sim F(N, T-N-K), \qquad (63.3)$$

where $\widehat{\sum}_\varepsilon$ is the unbiased residual covariance matrix, $\widehat{\vartheta}^2 = \bar{F}' \widehat{\sum}_F^{-1} \bar{F}$, $\bar{F}$ is a ($K \times 1$) vector of average returns of the factor portfolios ($= (1/T) \sum_{t=1}^T F_t$), $\widehat{\sum}_F$ is the covariance matrix of the factor portfolio returns. Here, $\widehat{\vartheta}$ is the ex post maximum Sharpe ratio of the K factor portfolios. The GRS test statistic of Equation 63.3 has a nice geometric interpretation. Since $\widehat{\alpha}' \widehat{\sum}_\varepsilon^{-1} \widehat{\alpha} = \widehat{\vartheta}^{*2} - \widehat{\vartheta}^2$ where $\widehat{\vartheta}^*$ is the ex post maximum Sharpe ratio of the N test assets and the K factor portfolios, the GRS test statistic equals

$$W = \left[\frac{T(T-N-K)}{N(T-K-1)} \right] \left[\left(\frac{1 + \widehat{\vartheta}^{*2}}{1 + \widehat{\vartheta}^2} \right) - 1 \right]$$
$$\sim F(N, T-N-K). \qquad (63.3a)$$

Thus the GRS test determines whether $\left| \widehat{\vartheta}^{*2} \right|$ is statistically greater than $\left| \widehat{\vartheta}^2 \right|$. As the squared Sharpe ratio of the tangency portfolio constructed from factor portfolios, $\widehat{\vartheta}^2$, decreases, the GRS test statistic increases, which is evidence against the mean-variance efficiency of some linear combination of the factor portfolios. If the given factor model is the one-factor model with the market index portfolio such as Standard and Poors 500 Index, the GRS test is to test the mean-variance efficiency of the given market index portfolio.

63.3 Tests Based on Generalized Methods of Moments (GMM)

63.3.1 Introduction of the GMM

The time-series tests based on individual t-tests and the GRS tests assume that asset returns or the error terms of Equation 63.1 are normally distributed. It is well-known, however, that asset returns are not normally distributed. In this circumstance, the generalized method of moments (GMM) developed by Lars Hansen (1982) is useful. The GMM refers to the estimation which uses the sample moment conditions from the population moment conditions. The main advantage of the GMM is that it makes empirical tests of an economic theory possible under a general framework. Specifically, the GMM makes nonlinear asset pricing models be empirically testable without linearization. The GMM is computationally convenient without strong distributional assumptions, and thus it can be used under serial correlation and conditional heteroskedasticity in making inferences. Moreover, it does not have to assume data generating processes. These advantages are the reason that the GMM is one of the most frequently applied methodologies in finance.

It should be mentioned, however, that the GMM estimators are only asymptotically valid. Ferson and Foerster (1994) find that a two-stage GMM approach tends to reject the models too often in a moderate sample size. Arellano and Bond (1991) also find that the estimated standard errors of the GMM estimators are severely downward biased in a small sample size. Ahn and Gadarowski (2004) show that asset pricing tests based on the GMM estimation reject the correct model too often. In other words, like other tests based on asymptotic estimators, tests based on the GMM estimation have too large Type I error.

63.3.2 Overview of the GMM Estimation

An economic model can be specified as a vector of population moment conditions: $E[g(x_t, \theta)] = E[g_t(\theta)] = 0$, where x_t is a vector of P variables for $t = 1,\ldots,T$, and θ is a parameter vector of K unknown parameters, $g(\cdot)$ is a vector of N functions, with the necessary order condition for identification such that $K \leq N$. Since the order condition is a necessary condition for identification, a failure of the order condition means that the model is not identified. When the model is over-identified, Hansen's (1982) J test can be implemented as using the over-identifying restrictions. The exactly identified model cannot be tested whether the model is correctly specified or not.

Let $g_T(\theta) = \frac{1}{T}\sum_{t=1}^{T} g_t(\theta)$ be the corresponding sample moments to the population moments. In the asset pricing test framework, $g_T(\theta)$ can be interpreted as a vector of pricing errors. Then, the GMM estimator $\widehat{\theta}$ for θ minimizes the following quadratic function with respect to θ.

$$Q = [g_T(\theta)]' \; W \; [g_T(\theta)], \qquad (63.4)$$

where W is a weighting matrix which is the positive definite. The weighting matrix W implies the weight to be given for each moment. If W is an identity matrix, the GMM treats all moments symmetrically. This means that all assets have the same degree of importance in estimating the parameters and that the objective function Q is simply to minimize the sum of squared pricing errors.

Hansen (1982) proposes the optimal weighting matrix as follows. The optimal weighting matrix produces the estimates with the smallest asymptotic variance.

When $E[g_t(\theta)] = plim_{T\to\infty} \frac{1}{T}\sum_{t=1}^{T} g_t(\theta) = p_{T\to\infty}^{lim} \; g_T(\theta)$ and the central limit theorem is applied,

$$\sqrt{T}g_T(\theta) \xrightarrow{d} N(0, V) \text{ as } T \to \infty, \qquad (63.5)$$

where $V = \sum_{j=-\infty}^{\infty} E[g(x_t, \theta) \; g(x_{t+j}, \theta)']$ which is a nonsingular covariance matrix. V is the spectral density matrix of $g_T(\theta)$. When $W = V^{-1}$, Hansen (1982) finds that the GMM estimates are efficient. A lower bound for the asymptotic variance of the GMM estimates can be achieved as choosing $W = V^{-1}$. Hansen (1982) shows that the asymptotic distribution of the GMM estimator is given by

$$\sqrt{T(\widehat{\theta} - \theta)} \xrightarrow{d} N(0, (\mathbf{D'V^{-1}D})^{-1}) \text{ as } T \to \infty, \qquad (63.6)$$

where $D = E\left[\frac{\partial g_t(\theta)}{\partial \theta'}\right] = p_{T\to\infty}^{lim} \frac{\partial g_T(\theta)}{\partial \theta'}$.

To calculate the efficient GMM estimate, the consistent estimator $\widehat{V}$ is needed. Newey and West (1987) and Cochrane (2005) show the estimation of V in form of spectral density matrix. A two-stage procedure can be employed to obtain the efficient GMM estimator. In the first-stage, a consistent estimator $\widehat{V}$ is obtained by using the identity matrix as the weighting matrix. In the second-stage, the efficient GMM estimator can be produced using $\widetilde{V}^{-1}$ as the weighting matrix. Cochrane (2005) and Hayashi (2000) describe in details. Tests for the model misspecification can be implemented as examining the extent of the pricing errors $g_T(\widehat{\theta})$. Hansen (1982) proposes J-statistics as follows

$$J = Tg_T(\widehat{\theta})V^{-1} g_T(\widehat{\theta}) \text{ and } J \xrightarrow{d} \chi^2(N-K) \text{ as } T \to \infty.$$
$$(63.7)$$

If the model is exactly identified, then $J = 0$.

Generally, the efficient GMM estimates are known to have poorer small sample properties. The model misspecification test based on the efficient GMM estimates also rejects the null hypothesis too often. Therefore, sufficiently large number of time-series return observations (T) relative to the number of assets (N) is required to obtain the consistent estimators. As the number of assets becomes large relatively to T, it is difficult to estimate the precise covariance matrix of returns. To avoid this problem, one approach is to group the assets into a small number of portfolios. Ferson and Foerster (1994) show that a GMM approach still tends to reject the models too often in moderate sample size. Other solutions are also proposed to improve the inference problem caused by the underestimation of the standard error of the GMM estimator. Ren and Shimotsu (2009) propose an improved method to compute the weighting matrix by applying the shrinkage method (Ledoit and Wolf (2003)). Windmeijer (2005) suggests the correction term to generate the more precise estimator of the standard error. Windmeijer (2005) adjusts the bias from the extra variation in small samples and reports the improved results.

63.3.3 Moments Conditions for the Asset Pricing Tests

Once the moment conditions are indentified, the estimation and the inference are straightforward. Generally, the optimization is performed by the numerical method. The closed-form solutions for the parameters are obtained only for some special cases in the GMM method.

The GMM method can be used for both the beta representation and the stochastic discount factor (SDF) representation in the asset pricing model. The asset pricing model under the beta representation is as follows:

$$E[r_t] = \gamma_1 \beta \text{ or } E[R_t] = \gamma_0 + \gamma_1 \beta, \quad (63.8)$$

where r_t is the excess return, R_t is the raw return, γ_0 is the return of the zero beta asset, γ_1 is the factor risk premium, and $\beta [= Cov(R_t, f_t)/\text{Var}(f_t)]$ is the sensitivity of the asset return to the factor. The SDF representation is given by

$$E[r_t m_t] = 0 \text{ or } E[R_t m_t] = 1, \quad (63.9)$$

where m_t is referred to as a stochastic discount factor. For example, the stochastic discount factor is given by $m_t = \lambda_0 + \lambda_1 f_t$ for a one-factor linear pricing model. If the model is true, then $m_t \in M_t$, where M_t is the set of the true stochastic discount factors.

The SDF representation using the GMM becomes popular in testing asset pricing models, since it can be used within the general framework to analyze either linear or nonlinear pricing models. However, there are some concerns that the generality of the SDF method using the GMM comes at the cost of efficiency in two aspects; estimation of the parameters and power in the specification tests. Kan and Zhou (1999) point out that the SDF method using the GMM has two problems when asset returns are generated by a linear factor model. The first is that the risk premium estimate from the SDF method is not reliable. The second problem is that the model specification test using the SDF method has too low power in detecting the misspecified model. But Jagannathan and Wang (2002) argue that the SDF method using the GMM is asymptotically as efficient as the beta method using the GMM in estimating the risk premium, and that the model specification test based on the SDF is also as powerful as the one based on the beta method using the GMM. They argue that Kan and Zhou's (1999) conclusion is inappropriate in that they ignored the risk premium measures in the two methods not identical and that they assumed the factor is predetermined. Jagannathan and Wang (2002) consider explicitly the additional moments about the SDF method and the transformation between the risk premium parameters in order to make a fair comparison between the two methods.

Let F_t and R_t be a vector of K risk factors and a vector of N test asset returns respectively. The pricing model can be denoted as

$$E[R_t] = \gamma 1 + B\Gamma, \quad (63.10)$$

where γ is the nonzero return of the zero-beta asset, $\mathbf{1}$ is an $(N \times 1)$ vector of ones, R_t is an $(N \times 1)$ vector of raw returns for the test assets, B is the factor loadings of the following time-series regression, $R_t = \varphi + Bf_t + \varepsilon_t$, the error term ε_t has zero mean and uncorrelated with the factors f_t. Then $\varphi = \gamma 1 + B(\Gamma - \mu_f)$, where μ_f is the mean of the factors. Using this restriction, the following restrictions can be obtained,

$$R_t = (\gamma 1 + B\Gamma - B\mu f) + Bf_t + \varepsilon_t \quad (63.11)$$

$$E[\varepsilon_t] = 0 \quad (63.12)$$

$$E[\varepsilon_t f'_t] = 0. \quad (63.13)$$

Now, the following $N + NK + K$ moment conditions can be made,

$$E[R_t - \gamma 1 - B(\Gamma - \mu_f + f_t)] = 0 \quad (63.14)$$

$$E\big[[r_t - \gamma 1 - B(\Gamma - \mu_f + f_t)]f_t'\big] = 0 \qquad (63.15)$$

$$E\big[f_t - \mu_f\big] = 0. \qquad (63.16)$$

Then, the unknown parameters to be estimated are γ, Γ, **B**, and μ_f. When the factor is the return on a portfolio of traded assets, it implies $\Gamma = \mu_f$ and the moment conditions are reduced as follows,

$$E[R_t - \gamma 1 - Bf_t] = 0 \qquad (63.17)$$

$$E[(R_t - \gamma 1 - Bf_t)f_t'] = 0. \qquad (63.18)$$

The moment conditions for the SDF representation can be derived from the linear asset pricing model. Using $E[R_t] = \gamma 1 + B\Gamma$ and $B = \Sigma_{Rf}\Sigma_{ff}^{-1}$, the following equation can be obtained

$$E\left[R_t\left(\frac{1}{\gamma} + \frac{\Gamma'\Sigma_{ff}^{-1}\mu_f}{\gamma} - \frac{\Gamma'\Sigma_{ff}^{-1}}{\gamma}f_t\right)\right] = 1. \qquad (63.19)$$

Then, the following SDF representation can be produced

$$E[R_t m_t] = 1, \qquad (63.20)$$

where $m_t = \lambda' x_t$, $\lambda = [\lambda_0 \lambda_1 \ldots \lambda_k]'$, and $x_t = [1 f_t']'$. Using these moment conditions, the parameters can be estimated, and the specification test can be implemented. The closed-form solution is known as follows.

$$\hat{\lambda} = (\hat{D}\hat{V}^{-1}\hat{D})\hat{D}\hat{V}^{-1}\bar{r}, \qquad (63.21)$$

where $\hat{D} = (1/T)\sum_{t=1}^{T}R_t x_t'$, $\bar{r} = (1/T)\sum_{t=1}^{T}r_t$, and $\hat{V}$ is a consistent estimator in Equation 63.5. The moment conditions for the conditional asset pricing are provided by Harvey (1989, 1991), Ferson and Harvey (1993), Jagannathan and Wang (1996), and Cochrane (1996).

63.3.4 The Hansen-Jagannathan Distance

Hansen and Jagannathan (1997) develop a distance metric which is referred as the Hansen-Jagannathan (HJ)-distance. They propose how to measure the distance between a true stochastic discount factor and the implied stochastic discount factor. The HJ-distance can be interpreted as the normalized maximum pricing error of the model for the test assets. If the implied stochastic discount factor from the model is included in the set of true stochastic

discount factor, then the HJ-distance is zero and the pricing error is none. To compute the HJ-distance, we can use simply the inverse of the second moment of the test asset returns as the weighting matrix, $E(R_t R_t')^{-1}$. They also provide the distribution of the HJ-distance.

The HJ-distance is defined as follows

$$\delta = \text{Min } ||y_t - m_t|| \text{ with respect to } m_t, \qquad (63.22)$$

where $E(m_t R_t) = 1$, R_t is the raw returns, y_t is a candidate SDF and $m_t \in M_t$, where M_t is the set of true SDF's. The measure of distance is the usual norm. The minimization problem can be written as the Lagrangian minimization problem

$$\delta^2 = \min_{m \in L^2, m \geq 0} \sup_{\tau \in R^n} \left\{ E(y_t - m_t)^2 - 2\tau'[E(m_t R_t) - 1] \right\}, \qquad (63.23)$$

where δ is the minimum distance from the candidate SDF to the true pricing kernel, L^2 is the space of all random variables with finite second moments. Hansen and Jagannathan (1997) show the following relation

$$y_t - m_t^* = \tau^{*'} R_t, \qquad (63.24)$$

where m_t^* and τ^* are the solutions for the Lagrangian minimization problem, and $\tau^* = E(R_t R_t')^{-1} E(y_t R_t - 1)$. Therefore, the HJ-distance is

$$\delta = ||y_t - m_t^*|| = \left[\tau^{*'} E(R_t R_t')\tau^*\right]^{\frac{1}{2}}. \qquad (63.25)$$

Using $\tau^* = E(R_t R_t')^{-1} E(y_t R_t - 1)$, the following equation can be produced.

$$\delta = \left[E(y_t R_t - 1)' E(R_t R_t')^{-1} E(y_t R_t - 1)\right]^{\frac{1}{2}}, \qquad (63.26)$$

where the pricing errors $g_t(\theta)$ can be defined as $E(y_t R_t - 1)$ here. Equation 63.26 is exactly the same as $\sqrt{Q}$ of Equation 63.4 with the weighting matrix $E(R_t R_t')^{-1}$ The sample analog can be as follows

$$\hat{\delta} = [g_T(\theta)]' \hat{G}^{-1} [g_T(\theta)], \qquad (63.27)$$

where $\hat{G} = (1/T)\sum_{t=1}^{T}R_t T_t'$, and $G = E(R_t R_t')$.

The HJ-distance means the smallest distance between the candidate SDF the true SDF. It can also be interpreted as the maximum pricing error of the considered test assets. Consider the following equations

$$|E(y_t R_{it}) - E(m_t^* R_{it})| = |E[(y_t - m_t^*) R_{it}]|$$
$$\leq E[(y_t - m_t^*)^2]^{\frac{1}{2}} E[R_{it}^2]^{\frac{1}{2}}. \quad (63.28)$$

The Cauchy-Schwartz inequality is applied to the last term. Then, Equation 63.25 can be rewritten as follows

$$\delta = ||y_t - m_t^*|| \geq \frac{|E(y_t R_{it}) - E(m_t^* R_{it})|}{||R_{it}}. \quad (63.29)$$

Therefore, the HJ-distance can also be interpreted as the normalized maximum pricing error for the considered test assets.

We estimate a vector of the unknown parameters θ and conduct the model specification test using the typical GMM procedure as follows

$$\hat{\theta}^{HJ} = arg\,\underset{\theta}{min}\,[g_T(\theta)]'\,\hat{G}^{-1}\,[g_T(\theta)]. \quad (63.30)$$

The distribution of $\hat{\theta}^{HJ}$ is the same as in Equation 63.6. However, the distribution of the model specification test statistic, which is T times the square of the HJ-distance, is not equal to that of the Hansen's J-statistic. Jagannathan and Wang (1996) suggest that the distribution of $T[g_T(\hat{\theta}^{HJ})]^2$ is a linear combination of χ^2 (63.1) variables. The distribution for the null hypothesis that the HJ-distance δ is zero is given by

$$T[\delta(\hat{\theta}^{HJ})]^2 \xrightarrow{d} \sum_{j=1}^{N-K-1} \varphi_j \pi_j \text{ as } T \to \infty, \quad (63.31)$$

where π_j is a random variable that follows χ^2 (63.1), and φ_j is the nonzero eigenvalues of the following matrix

$$\Lambda = V^{1/2} G^{-1/2} \Big(I - (G^{-1/2})' D (D' G^{-1} D)^{-1} D' G^{-1/2}\Big)$$
$$(G^{-1/2})' (V^{1/2})', \quad (63.32)$$

where $V^{1/2}$ and $G^{1/2}$ are the upper triangular matrices in the Cholesky decompositions of V and G. Jagannathan and Wang (1996) suggest that the empirical p-value can be obtained by comparing $T[\delta(\hat{\theta}^{HJ})]^2$ to $\sum_{j=1}^{N-K-1} \varphi_j \pi_j$ which is computed as random draws from a χ^2 (63.1) distribution. The empirical p-value of the HJ-distance can be computed from the following function.

$$\text{Empirical p-value} = \frac{1}{I} \sum_{i=1}^{I} f(x_i), \quad (63.33)$$

where $x_i = \left(\sum_{j=1}^{n-k-1} \varphi_j \pi_{ji}\right) - T[g_T(\hat{\theta}^{HJ})]^2$, $f(x_i)$ is the function which returns 1 if $x_i \geq 0$ and 0 otherwise. Jagannathan and Wang (1996) set I to 5000 in their paper. According to Ahn and Gadarowski (2004), tests based on this empirical p-value reject too often the correct models, since the computation of the empirical p-value depends on the eigenvalues from the estimate of Λ and $\hat{V}$ has the poor finite sample property.

63.3.5 An Equality Test for the HJ-Distance

Kan and Robotti (2009) develop the method to test the HJ-distance equality of the two competing linear asset pricing models. They analyze the case of both the nested and non-nested models whether the HJ-distances of the two competing models are equal. This section introduces the general case when both non-nested models are misspecified and the both stochastic discount factors are not equal.

Let y_1 and y_2 be two competing models. δ_1 and δ_2 of Equation 63.22 in the two models are nonzero. All subscript means the model type. Let $d_t = q_{1t} - q_{2t}$, where $q_{1t} = 2u_{1t}y_{1t} - u_{1t}^2 + \delta_1^2$, $q_{2t} = 2u_{2t}y_{2t} - u_{2t}^2 + \delta_2^2$ with $u_{1t} = g_1' G^{-1} R_t$ and $u_{2t} = g_2' G^{-1} R_t$. Then

$$\sqrt{T}\Big[\hat{\delta}_1^2 - \hat{\delta}_2^2 - (\delta_1^2 - \delta_2^2)\Big] \xrightarrow{d} N(0, v_d), \quad (63.34)$$

where $v_d = \sum_{j=-\infty}^{\infty} E[d_t d_{t+j}]$ and $d_t = 2u_{1t}y_{1t} - u_{1t}^2 - 2u_{2t}y_{2t} + u_{2t}^2$. Under the null hypothesis $H_0 : \delta_1^2 = \delta_2^2 \neq 0$,

$$\sqrt{T}(\hat{\delta}_1^2 - \hat{\delta}_2^2) \xrightarrow{d} N(0, v_d) \quad (63.35)$$

63.4   Cross-Sectional Tests

63.4.1 A Risk Premia Estimation Through Two-Pass Regressions

Traditional asset pricing theories such as the CAPM (Sharpe, 1964; Lintner, 1965; Black, 1972), the APT (Ross, 1976, the Intertemporal CAPM (Merton, 1973), and the Consumption CAPM (Breeden, 1979) imply that the difference in expected returns across assets should be explained by their covariances with (systematic) risk factors or their factor loadings. When asset returns are generated from a K-factor model, their expected returns are represented by a linear

combination of the factor loadings or betas, as in Equation 63.2,

$$E(r_{it}) = \gamma' \beta_i \text{ for } i = 1, 2, \ldots, N. \quad (63.2)$$

Since the factor loadings, β_i, are not directly observable, it is natural to test the cross-sectional relation between expected returns and factor ladings in two stages. In the first stage, beta estimates are obtained from time-series regressions of Equation 63.1,

$$r_{it} = R_{it} - R_{ft} = \alpha_i + \beta_i' F_t + \varepsilon_{it}, E(\varepsilon_{i,t}|F_t) = 0. \quad (63.36)$$

In practice, beta estimates in the first stage regression are computed using the OLS and are given as follows

$$\hat{\beta}_i = \widehat{Var(F)}^{-1} \widehat{Cov(F, r_i)}, \quad (63.37)$$

where $\widehat{Var(F)} = (1/T) \sum (F_t - \bar{F})' (F_t - \bar{F})$ and $\widehat{Cov(F, r_i)} = (1/T) \sum (F_t - \bar{F})(r_{it} - \bar{r}_i)$. In the second stage, one runs a cross-sectional regression (CSR) of excess average returns of N assets on their estimated betas obtained from the first stage,

$$\bar{r} = \hat{\beta}\gamma + e, \quad (63.38)$$

where $\bar{r}$ is an $(N \times 1)$ average returns, $\hat{\beta} = [\hat{\beta}_1, \hat{\beta}_2, \ldots, \hat{\beta}_N]'$ is an $(N \times K)$ beta estimates matrix, and e is an $(N \times 1)$ residual returns with mean zero and covariance matrix $\mathbf{Var}(e) = \Sigma_e$.

Under the classical linear model assumptions, the OLS risk premia estimates of Equation 63.38 is given as

$$\hat{\gamma}_{\text{OLS}} = (\hat{\beta}'\hat{\beta})^{-1}\hat{\beta}'\bar{r}. \quad (63.39)$$

However, obtaining the correct distribution of $\hat{\gamma}_{\text{OLS}}$ in finite samples is not so trivial, since the explanatory variables are measured with error and the least squares estimates of Equation 63.39 are subject to the errors-in-variables (EIV) bias. If we ignore the EIV bias and regard $\hat{\beta}$ as the true beta variable $\boldsymbol{\beta}$ for a while, then the distribution of the OLS estimator of Equation 63.39 is

$$\hat{\gamma}_{OLS} \sim N(\gamma, (\beta'\beta)^{-1} \beta' \text{Var}(e)\beta(\beta'\beta)^{-1}). \quad (63.40)$$

Since $Var(e) = Var(\bar{r} - \beta\gamma) = Var(\alpha + \beta\bar{F} + \bar{\varepsilon} - \beta\gamma) = Var[\beta(\bar{F} - \gamma) + \bar{\varepsilon}]$ the error covariance of the cross-sectional regression in (63.38) is

$$Var(e) = \frac{1}{T}(\beta\Sigma_F\beta' + \Sigma_\varepsilon), \quad (63.41)$$

where Σ_F is the factor covariance and Σ_ε is the error covariance in the time-series regression. Therefore, Equation 63.40 can be rewritten as

$$\hat{\gamma}_{OLS} \sim N\left(\gamma, \frac{1}{T}\left[(\beta'\beta)^{-1}\beta'\Sigma_\varepsilon\beta(\beta'\beta)^{-1} + \Sigma_F\right]\right). \quad (63.42)$$

See also Cochran (2004). For statistical inference, each variable in Equation 63.42 can be replaced with its time-series sample counterpart.

63.4.2 The GLS Estimation of Risk Premia

The OLS risk premia estimation in the previous section assumes that the residuals are cross-sectionally uncorrelated. However, since this assumption could be too strong, risk premia can be estimated by the generalized least squares (GLS) in which residuals are weighted in a way to ease heteroskedasticity. The GLS estimate of risk premia is[1]

$$
\begin{aligned}
\hat{\gamma}_{GLS} &= [\beta'Var(e)^{-1}\beta]^{-1}\beta'Var(e)^{-1}\bar{r} \\
&= \left[\beta'(\beta\Sigma_F\beta' + \Sigma_\varepsilon)^{-1}\beta\right]^{-1}\beta'(\beta\Sigma_F\beta' + \Sigma_\varepsilon)^{-1}\bar{r} \\
&= (\beta'\Sigma_\varepsilon^{-1}\beta)^{-1}\beta'\Sigma_\varepsilon^{-1}\bar{r}.
\end{aligned}
\quad (63.43)
$$

The distribution of the GLS estimator of Equation 63.43 is

$$\hat{\gamma}_{GLS} \sim N\left(\gamma, \frac{1}{T(\beta'\Sigma_\varepsilon^{-1}\beta + \Sigma_F)}\right). \quad (63.44)$$

63.4.3 The Errors-in-Variables Problem

63.4.3.1 Corrections for the Standard Errors

Previous discussions simply ignore the fact that beta estimates obtained in the first-pass are not true betas but are measured with error (Shanken, 1992). It is well known that the beta estimate in time-series regression is T-consistent (as T goes to infinity, the estimation error of beta estimates goes to zero). In other words, as the number of time-series observations (T) goes to infinity and they are stationary, the

---

[1] Let $\mathbf{A} = \mathbf{I} + \beta'\Sigma_\varepsilon^{-1}\boldsymbol{\beta}\boldsymbol{\Sigma}_\mathbf{F}$. Then, $\hat{\gamma}_{\text{GLS}} = \left[\mathbf{A}\beta'\left(\beta\sum_\mathbf{F}\beta' + \sum_\varepsilon\right)^{-1}\beta\right]^{-1}$ $\mathbf{A}\beta'\left(\beta\sum_\mathbf{F}\beta' + \sum_\varepsilon\right)^{-1}\bar{r}$. Since, $\mathbf{A}\beta' = \beta'\Sigma_\varepsilon^{-1}(\Sigma_\varepsilon + \beta\Sigma_\mathbf{F}\beta')$, $\hat{\gamma}_{\text{GLS}} = (\beta'\Sigma_\varepsilon^{-1}\beta)^{-1}\boldsymbol{\beta}\Sigma_\varepsilon^{-1}\bar{r}$.

beta estimate converges to its true beta. As long as we obtain T-consistent beta estimates, the CSR least squares estimates of risk premia are N-consistent if the number of test assets in the CSR (N) is large. However, since return observations show nonstationarity (see Kim and Kon (1996, 1999)) and thus it is difficult to increase T in estimating betas, it would be hard to obtain T-consistent beta estimates, and accordingly, the least squares estimates of Equations 63.39 and 63.43 and their standard errors are not N-consistent and are biased.

Shanken (1992) suggests a method of correcting for the bias of the standard errors of the CSR least squares estimates in the two-pass methodology. Assuming the model given in Equation 63.36 is correct, Shanken (1992) provides the correction for the variance of the CSR risk premia estimates as follows.

$$Var(\widehat{\gamma}_{OLS}) = \frac{1}{T}\left[(1 + \gamma'\Sigma_{\mathbf{F}}^{-1}\gamma)(\beta'\beta)^{-1}\beta'\Sigma_{\varepsilon}\beta(\beta'\beta)^{-1} + \Sigma_F\right] \quad (63.45)$$

$$Var(\widehat{\gamma}_{GLS}) = \frac{1}{T}\left[(1 + \gamma'\Sigma_{\mathbf{F}}^{-1}\gamma)(\beta'\Sigma_{\varepsilon}^{-1}\beta)^{-1} + \Sigma_F\right]. \quad (63.46)$$

Notice that t-values of the CSR estimates tend to be overstated due to the measurement errors of the explanatory variables $\widehat{\beta}$. Since the corrected variance of (63.45) or (63.46) is increased by adding the correction term $\gamma'\Sigma_{\mathbf{F}}^{-1}\gamma$, the above correction attempts to lessen the EIV bias in the standard error of the estimates.

63.4.3.2 Corrections for the Risk Premium Estimate

The Shanken correction in (63.45) or (63.46) can be applied only to make a correction for the EIV bias of the standard errors of the CSR risk premia estimates, not of the estimates themselves (Kim, 1995). Instead of correcting the variance as in Shanken (1992), Kim (1995) provides a direct correction for the EIV bias of the CSR market risk premium estimate within the Fama and MacBeth methodology. Suppose we have the following CSR model to be estimated at time t with an estimated beta variable and a firm characteristic variable (e.g., firm size or book-to-market) measured without error at $t - 1$,

$$R_t = \gamma_{0t} + \gamma_{1t}\widehat{\beta}_{t-1} + \gamma_{2t}V_{t-1} + \varepsilon_t. \quad (63.47)$$

In the above equation, the beta variable is measured with error. The beta variable is typically obtained from the time series regression (the first pass) of a firm's returns on the market returns by using return observations from $t - T$ to $t - 1$. When the beta variable is measured error as in Equation 63.47, it is well known that the EIV problem is present. Thus, the EIV problem occurs in the two-pass methodology. The least

squares estimation of the CSR in Equation 63.47 results in the underestimation of the role of market beta and the overestimation of the role of the firm characteristic variables.

To make correction for the EIV problem, Kim (1995) provides an EIV corrected estimators for the CSR coefficients of Equation 63.47, $\widehat{\gamma}_{0t}, \widehat{\gamma}_{1t}$, and $\widehat{\gamma}_{2t}$, which are N-consistent.

$$\widehat{\gamma}_{1t} = C_{1t}\widehat{\gamma}_{1t}^{LS} \quad (63.48)$$

$$\widehat{\gamma}_{2t} = C_{2t}\widehat{\gamma}_{2t}^{LS} \quad (63.49)$$

$$\widehat{\gamma}_{0t} = \widehat{\gamma}_{0t}^{LS} - (C_{1t} - 1)\widehat{\gamma}_{1t}^{LS}\bar{\widehat{\beta}}_{t-1} - (C_{2t} - 1)\widehat{\gamma}_{2t}^{LS}\bar{V}_{t-1} \quad (63.50)$$

where

$$C_{1t} = \frac{1}{\left[1 - \frac{1}{2}\left(\frac{m_{RR}\left(1 - \hat{\rho}_{RV}^2\right)}{\delta_t m_{\hat{\beta}\hat{\beta}}\left(1 - \hat{\rho}_{\hat{\beta}V}^2\right)} + 1\right)\left(1 - (1 - Q)^{\frac{1}{2}}\right)\right]} \geq 1$$

$$Q = \frac{1 - \hat{\rho}_{R\hat{\beta}\cdot V}^2}{\left[\frac{1}{2} + \frac{1}{4}\left(\frac{\delta_t m_{\hat{\beta}\hat{\beta}}\left(1 - \hat{\rho}_{\hat{\beta}V}^2\right)}{m_{RR}\left(1 - \hat{\rho}_{RV}^2\right)} + \frac{m_{RR}\left(1 - \hat{\rho}_{RV}^2\right)}{\delta_t m_{\hat{\beta}\hat{\beta}}\left(1 - \hat{\rho}_{\hat{\beta}V}^2\right)}\right)\right]}$$

$$C_{2t} = 1 - \frac{(C_{1t} - 1)\left\{(\hat{\rho}_{R\hat{\beta}}\hat{\rho}_{\hat{\beta}V}/\hat{\rho}_{RV}) - \hat{\rho}_{\hat{\beta}}^2\right\}}{1 - (\hat{\rho}_{R\hat{\beta}}\hat{\rho}_{\hat{\beta}V}/\hat{\rho}_{RV})}$$

and $\delta_t = T\hat{\sigma}_{m,t-1}^2$ where $\hat{\sigma}_{m,t-1}^2$ is the MLE of the market variance computed using market returns from $t - T$ to $t - 1$, $m_{xy} = (1/N)(x - \iota\tilde{x})'\hat{\Sigma}_s^{-1}(y - \iota\tilde{y})$, $\tilde{x} = \Sigma_{i=1}^N\Sigma_{j=1}^N w_{ij}x_i/\Sigma_{i=1}^N\Sigma_{j=1}^N w_{ij}$, w_{ij} is the (i,j)-th element of $\hat{\Sigma}_\varepsilon^{-1}$, $\hat{\rho}_{xy} = m_{xy}/\left(m_{xx}m_{yy}\right)^{1/2}$ and $\hat{\rho}_{R\hat{\beta}\cdot V}^2 = \left(\hat{\rho}_{R\hat{\beta}} - \hat{\rho}_{RV}\right)^2/\left\{\left(1 - \hat{\rho}_{\hat{\beta}V}^2\right)\left(1 - \hat{\rho}_{RV}^2\right)\right\}$. Here, $\hat{\gamma}_t^{LS}$ is the least squares estimate. Note that $m_{..}$ is the cross-sectional sample second moment and $\hat{\rho}_{..}$ is thus the cross-sectional correlation coefficient.

Since the EIV-bias correction term C_{1t} is greater than one, this term makes correction for the underestimation of the least squares estimate, $\hat{\gamma}_{1t}^{LS}$. Also, since the term C_{2t} is usually less than one, this term makes correction for the overestimation of the least squares estimate of the coefficient on the firm characteristic variable such as firm size and book-to-market, $\hat{\gamma}_{2t}^{LS}$. Following the seminal works of Black, Jensen and Scholes (1972) and Fama and MacBeth (1973), portfolio grouping procedures are prevalent to lessen the EIV problem. Aside the fact that the portfolio grouping procedure does not completely remove the problem, however, it significantly

reduces the sample size (N), henceforth weakens the power of the tests. In this regard, a direction correction for the EIV problem like Kim (1995) is important for the use of all individual assets as test assets.

63.5 Summary and Concluding Remarks

This article reviews the methodologies of testing asset pricing models. We provide some explanations for two testing methodologies dominantly used in the literature; time-series regression tests and cross-sectional regression tests. We explain individual t-test and the joint F-test by Gibbons, Ross, and Shanken (1989) which are used in time-series tests. We also explain the two-pass test methodology that is used in cross-sectional test, and discuss the errors-in-variables problem which occurs inevitably in the two-pass methodology. Moreover, we provide some explanations of tests based on the GMM estimation and tests based on the Hansen-Jagannathan (1997) distance.

Alternative Methods for Estimating Firm's Growth Rate

64

Ivan E. Brick, Hong-Yi Chen, and Cheng-Few Lee

Abstract

The most common valuation model is the dividend growth model. The growth rate is found by taking the product of the retention rate and the return on equity. What is less well understood are the basic assumptions of this model. In this paper, we demonstrate that the model makes strong assumptions regarding the financing mix of the firm. In addition, we discuss several methods suggested in the literature on estimating growth rates and analyze whether these approaches are consistent with the use of using a constant discount rate to evaluate the firm's assets and equity. The literature has also suggested estimating growth rate by using the average percentage change method, compound-sum method, and/or regression methods. We demonstrate that the average percentage change is very sensitive to extreme observations. Moreover, on average, the regression method yields similar but somewhat smaller estimates of the growth rate compared to the compound-sum method. We also discussed the inferred method suggested by Gordon and Gordon (The Financial Analysts Journal 53: 52–61, 1997) to estimate the growth rate. Advantages, disadvantages, and the interrelationship among these estimation methods are also discussed in detail.

Compound sum method • Discount cash flow model • Growth rate • Internal growth rate • Sustainable growth rate

64.1 Introduction

One of the more highly used valuation models is that developed by Gordon and Shapiro (1956) and Gordon (1962) known as the dividend growth model. In security analysis and portfolio management, growth rate estimates of earnings, dividends, and price per share are important factors in determining the value of an investment or a firm. These publications demonstrate that the growth rate is found by taking the product of the retention rate and the return on equity. What is less well understood are the basic assumptions of this model. In this paper, we demonstrate that the model makes strong assumptions regarding the financing mix of the firm.

In addition, we will also discuss several methods suggested in the literature on estimating growth rates. We will analyze whether these approaches are consistent with the use of using a constant discount rate to evaluate the firm's assets and equity.

In particular, we will demonstrate that the underlying assumptions of the internal growth rate model (whereby no external funds are used to finance growth) is incompatible with the constant discount rate model of valuation.

The literature has also suggested estimating growth rate by taking the average of percentage change of dividends over a sample period, taking the geometric average of the change in dividends or using regression analysis to estimate the growth rate (e.g. Lee et al., 2009, 2012, 2000; Ross et al., 2010). Gordon and Gordon (1997) suggest first using the Capital Asset Pricing Model (CAPM) to determine the cost of equity of the firm and then using the dividend growth model to infer the growth rate. Advantages, disadvantages, and the interrelationship among these estimation methods are also discussed in detail.

This paper is organized as follows. In Section 64.2 we present the Gordon and Shapiro model (1956). We discuss the inherent assumptions of the model and its implied method to estimate the growth rate. Section 64.3 analyzes the internal growth rate and sustainable growth rate models. Section 64.4 describes leading statistical methods for estimating firm's growth rates. We will also present the inferred method suggested by Gordon and Gordon (1997) to estimate the growth rate. Concluding remarks appear in Section 64.5.

64.2 The Discounted Cash Flow Model and the Gordon Growth Model

The traditional academic approach to evaluate a firm's equity is based upon the constant discount rate method. One approach uses the after-tax weighted average cost of capital as a discount rate. This model is expressed as:

$$
Value\ of\ Equity = \sum_{t=1}^{\infty} \frac{CF_{ut}}{(1 + ATWACOC)^t} - Debt_t, \qquad (64.1)
$$

where CF_{ut} is the expected unlevered cash flow of the firm at time t and $Debt_t$ is the market value of debt outstanding. $ATWACOC$ equals $L(1 - \tau)R_d + (1 - L)r$ where L is the market value proportion of debt, τ is the corporate tax rate, R_d is the cost of debt and r is the cost of equity. The first term on the right hand side of Equation 64.1 is the value of the assets. Subtracting out the value of debt yields the value of equity. The price per share is therefore the value of equity divided by the number of shares outstanding. Alternatively, the value of equity can be directly found by discounting the dividends per share by the cost of equity, or more formally:

$$
Value\ of\ Common\ Stock\ (P_0) = \sum_{t=1}^{\infty} \frac{d_t}{(1 + r)^t}, \qquad (64.2)
$$

where d_t is the dividend per share at time t. Boudreaux and Long (1979), and Chambers et al. (1982) demonstrate the equivalence of these two approaches assuming that the level of that the level of debt is a constant percentage of the value of the firm.[1] Accordingly:

$$
\frac{\sum_{t=1}^{\infty} \frac{X_t}{(1+ATWACOC)^t} - Debt_t}{\#\ of\ Shares\ Outstaning} = \sum_{t=1}^{\infty} \frac{d_t}{(1 + r)^t} \qquad (64.3)
$$

If we assume that dividends per share grow at a constant rate g, then Equation 64.2 is reduced to the basic dividend growth model[2]:

$$
P_0 = \frac{d_1}{(r - g)}. \qquad (64.4)
$$

Gordon and Shapiro (1956) demonstrates that if b is the fraction of earnings retained within the firm, and r is the rate of return the firm will earn on all new investments, then $g = br$. Let I_t denote the level of new investment at time t. Because growth in earnings arises from the return on new investments, earnings can be written as:

$$
E_t = E_{t-1} + rI_{t-1}, \qquad (64.5)
$$

where E_t is the earnings in period t.[3] If the firm's retention rate is constant and used in new investment, then the earnings at time t is

$$
\begin{aligned}
E_t &= E_{t-1} + rbE_{t-1} \\
&= E_{t-1}(1 + rb).
\end{aligned} \qquad (64.6)
$$

Growth rate in earnings is the percentage change in earnings and can be expressed as

$$
\begin{aligned}
g_E &= \frac{E_t - E_{t-1}}{E_{t-1}} \\
&= \frac{E_{t-1}(1 + rb) - E_{t-1}}{E_{t-1}}. \\
&= rb
\end{aligned} \qquad (64.7)
$$

If a constant proportion of earnings is assumed to be paid out each year, the growth in earnings equals the growth in dividends, implying $g = br$. It is worthwhile to examine the

---

[1] See Brick and Weaver (1984, 1997) concerning the magnitude of error in the valuation using a constant discount rate when the firm does not maintain a constant market based leverage ratio.

[2] Gordon and Shapiro's (1956) model assume that dividends were paid continuously and hence $P_0 = d_1/(r - g)$.

[3] Earnings in this model are defined using the cash-basis of accounting and not on an accrual basis.

implication of this model for the growth in stock prices over time. The growth in stock price is

$$g_P = \frac{P_{t+1} - P_t}{P_t}. \tag{64.8}$$

Recognizing that P_t and P_{t+1} can be defined by Equation 64.4, while noting that d_{t+2} is equal to $d_{t+1}(1 + br)$ then:

$$
\begin{aligned}
g_P &= \frac{\dfrac{d_{t+2}}{k - rb} - \dfrac{d_{t+1}}{k - rb}}{\dfrac{d_{t+1}}{k - rb}} \\
&= \frac{d_{t+2} - d_{t+1}}{d_{t+1}} \\
&= \frac{d_{t+1}(1 + br) - d_{t+1}}{d_{t+1}}. \\
&= br \tag{64.9}
\end{aligned}
$$

Thus, under the assumption of a constant retention rate, for a one-period model, dividends, earnings, and prices are all expected to grow at the same rate.

The relationship between the growth rate, g, the retention rate, b, and the return on equity, r, can be expanded to a multi-period setting as the following numerical examples illustrates. In the first example, we assume that the book value of the firm's assets equal the market value of the firm. We will assume that the growth rate of the firm sales and assets is 4% and the tax rate is equal to 40%. The book value of the assets at time 0 is $50 and we assume a depreciation rate of 10% per annum. The amount of debt outstanding is $12.50 and amount of equity outstanding is $37.50. We assume that the cost of debt, R_d, is 12% and the cost of equity, r, is 25%, implying an $ATWACOC$ of 20.55%. The expected dividend at $t = 1$, d_1, must satisfy Equation 64.4. That is, $37.50 = d_1/(0.25 - 0.04)$.

The unlevered cash flow is defined as Sales less Costs (excluding the depreciation expense) less Investment less the tax paid. Tax paid is defined as the tax rate (which we assume to be 40%) times Sales minus Costs minus the Depreciation Expense. Recognizing that the value of the firm is given by $CF_{u1}/(ATWACOC - g)$, if firm value is $50, $g = 4\%$ and $ATWACOC$ is 20.55%, then the expected unlevered cash flow is at time 1 is $8.28. We assume that the asset turnover ratio is 1.7. Hence, if assets at time 0 is $50, the expected sales at time 1 is $85. To obtain the level of investment, note that the depreciation expense at time 1 is $5. If the book value of assets equals $52, then the firm must invest $7. To obtain an expected unlevered cash flow at $t = 1$ of $8.28, the Gross Profit Margin is assumed to be approximately 26.03%, resulting in expected costs at time 1 of $62.88. The interest expense at time 1, is the cost of debt times the amount of debt outstanding at time zero, or $1.50. The Earnings Before Taxes (EBT) is defined as Sales – Costs – Interest Expense – Depreciation Expense,

which equals $15.63 at time 1. 40% of EBT is the taxes paid or $6.25 resulting in a net income (NI) of $9.38. ROE, which equals Net Income/Book Value of Equity at the beginning of the period is 25%. Since the aggregate level of dividends at time 1 is $7.88, then the dividend payout ratio $(1 - b)$ is 84%. Note that b is therefore equal to 16% and $b \times ROE = 4\%$.[4]

Further note that the firm will increase its book value of equity via retention of NI by $1.50 ($RE$ in the table). In order to maintain a leverage ratio of 25%, the firm must increase the level of debt from time 0 to time 1 by $0.50. The entries for time periods 2–5 follow the logical extension of the above discussion, and as shown in the table, the retention rate b is 16% and $ROE = 25\%$ for each period. Again the product of b and ROE results in the expected growth rate of 4%. Further note, that $g = 4\%$ imply that sales, costs, book value of asset, depreciation, unlevered cash flow, cash flow to stockholders, value of debt and value of equity to increase by 4% per annum.

Investors may use a one-period model in selecting stocks, but future profitability of investment opportunities plays an important role in determining the value of the firm and its EPS and dividend per share. The rate of return on new investments can be expressed as a fraction, c (perhaps larger than 1), of the rate of return security holders require (r):

$$k = cr. \tag{64.10}$$

Substituting this into the well-known relationship that $r = \frac{d_1}{P_0} + g$ and rearranging, we have

$$k = \frac{(1 - b)E_1}{(1 - cb)P_0}. \tag{64.11}$$

If a firm has no extraordinary investment opportunities $(r = k)$, then $c = 1$ and the rate of return that security holders require is simply the inverse of the stock's price to earnings ratio. In our example of Table 64.1, NI at time 1 is $9.38 and the value of equity at time 0 is $37.50. The ratio of these two numbers (which is equivalent to EPS/P) is ROE or 25%.

On the other hand, if the firm has investment opportunities that are expected to offer a return above that required by the firm's stockholders ($c > 1$), the earnings to price ratio at which the firm sells will be below the rate of return required by investors. To illustrate consider the following example whereby market value of the firm and equity is greater than its book value. This example is depicted in Table 64.2. The basic assumptions of the model is as

---

[4] Generally, practitioners define ROE as the ratio of the Net Income to the end of year Stockholders Equity. Here we are defining ROE as the ratio of the Net Income to the beginning of the year Stockholders Equity. Brick et al. (2012) demonstrate that the practitioner's definition is one of the sources for the Bowman Paradox reported in the Organization Management literature.

follows: We will assume that the growth rate of the firm sales and book value of the assets is 4%. The book value of the assets at time 0 is again $50 and we assume a depreciation rate of 10% per annum. However, note that the market value of the firm is $60. The entries for Debt and Equity represent market values. The amount of debt outstanding is $12.50 and amount of equity outstanding is now $47.50. We assume that the cost of debt, R_d, is 12% and the cost of equity, r, is 25%, implying an *ATWACOC* of 21.29%. For the valuation of the firm to be internally consistent, the unlevered cash flow at time 1 is $10.38. Similarly, the value of equity to be internally consistent, the expected dividends at t = 1 is $9.98. Note that net income is $11.88 implying a dividend payout ratio of 84% and a retention rate of 16%. The *book value based ROE*, k, is found by taking the net income divided by the book value of equity. In our example, implied book value of equity is $37.50. Hence, $k = 31.68\%$, implying that the book value ROE is greater than the cost of equity which is the required rate of return. But g is given by the *market value based ROE* which is defined as Net Income over market value of equity. That is $r = 25\%$. Note again, br is 4%.

An investor could predict next year's dividends, the firm's long-term growth rate, and the rate of return stockholders require (perhaps using the *CAPM* to estimate r) for holding the stock. Equation 64.4 could then be solved for the theoretical price of the stock that could be compared with its present price. Stocks that have theoretical prices above actual price are candidates for purchase; those with theoretical prices below their actual price are candidates for sale or for short sale.

64.3   Internal Growth Rate and Sustainable Growth Rate Models

The internal growth rate model assumes that the firm can only finance its growth by its internal funds. Consequently, the cash to finance growth must come from only retained earnings. Therefore, retained earnings can be expressed as

$$
\begin{aligned}
\text{Retained Earnings} &= \text{Earnings} - \text{Dividends} \\
&= \text{Profit Margin} \times \text{Total Sales - Dividends}, \\
&= p(S + \Delta S) - p(S + \Delta S)(1 - b) \\
&= pb(S + \Delta S)
\end{aligned}
\tag{64.12}
$$

where
$p=$ the profit margin on all sales;
$S=$ annual sales; and
$\Delta S=$ the increase in sales during the year.

Because retained earnings is the only source of new funds, the use of cash represented by the increase in assets must equal the retained earnings:

$$
\text{Uses of Cash} \; = \; \text{Sources of Cash}
$$

$$
\text{Increases in Assets} \; = \; \text{Retained earnings}
$$

$$
\begin{aligned}
\Delta ST &= p(S + \Delta S)b \\
&= pbS + pb\Delta S,
\end{aligned}
$$

$$
\Delta S[T - pb] = pSb,
$$

$$
\frac{\Delta S}{S} = \frac{pb}{T - pb},
\tag{64.13}
$$

where $T =$ the ratio of total assets to sales. If we divide both numerator and denominator of Equation 64.13 by T and make rearrange the terms, then we can show that the internal growth rate is:

$$
\begin{aligned}
g &= \frac{\Delta S}{S} \\
&= \frac{pb/T}{1 - pb/T} \\
&= \frac{b \times ROA}{1 - b \times ROA},
\end{aligned}
\tag{64.14}
$$

where *ROA* is the return on assets. The internal growth rate is the maximum growth rate that can be achieved without debt or equity kind of external financing. But note this assumption of not issuing new debt or common stock to finance growth is inconsistent with the basic assumption of the constant discount rate models that the firm maintains a constant market based leverage ratio. Hence, this model cannot be used to estimate the growth rate and be employed by the Gordon Growth Model.

Higgins (1977, 1981, 2008) has developed a sustainable growth rate under assumption that firms can generate new funds by using retained earnings or issuing debt, but not issuing new shares of common stock. Growth and its management present special problems in financial planning. From a financial perspective, growth is not always a blessing. Rapid growth can put considerable strain on a company's resources, and unless management is aware of this effect and takes active steps to control it, rapid growth can lead to bankruptcy. Assuming a company is not raising new equity, the cash to finance growth must come from retained earnings and new borrowings. Further, because the company wants to maintain a target debt-to-equity ratio equal to L, each dollar added to the owners' equity enables it to increase its indebtedness by $L. Since the owners'

equity will rise by an amount equal to retained earnings, the new borrowing can be written as:

$$
\begin{aligned}
\text{New Borrowings} &= \text{Retained Earnings} \\
&\quad \times \text{Target Debt-to-Equity Ratio} \\
&= pb(S + \Delta S)L.
\end{aligned}
$$

The use of cash represented by the increase in assets must equal the two sources of cash (retained earnings and new borrowings)[5]:

$$
\text{Uses of Cash} = \text{Sources of Cash}
$$

$$
\text{Increases in Assets} = \text{Retained Earnings} + \text{New Borrowing}
$$

$$
\begin{aligned}
\Delta ST &= pb(S + \Delta S) + pb(S + \Delta S)L \\
&= pb(1+L)S + pb(1+L)\Delta S
\end{aligned}
$$

$$
\Delta S[T - pb(1+L)] = pb(1+L)S
$$

$$
\begin{aligned}
g &= \frac{\Delta S}{S} \\
&= \frac{pb(1+L)}{T - pb(1+L)}.
\end{aligned}
\tag{64.15}
$$

In Equation 64.15 the $\Delta S/S$ or g is the firm's sustainable growth rate assuming no infusion of new equity. Therefore, a company's growth rate in sales must equal the indicated combination of four ratios, p, b, L, and T. In addition, if the company's growth rate differs from g, one or more of the ratios must change. For example, suppose a company grows at a rate in excess of g, then it must either use its assets more efficiently, or it must alter its financial policies. Efficiency is represented by the profit margin and asset-to-sales ratio. It therefore would need to increase its profit margin (p) or decrease its asset-to-sales ratio (T) in order to increase efficiency. Financial policies are represented by payout or leverage ratios. In this case, a decrease in its payout ratio (1-b) or an increase in its leverage (L) would be necessary to alter its financial policies to accommodate a different growth rate. It should be noted that increasing efficiency is not always possible and altering financial policies are not always wise.

If we divide both numerator and denominator of Equation 64.15 by T and rearrange the terms, then we can show that the sustainable growth rate can be shown as

$$
\begin{aligned}
g &= \frac{\Delta S}{S} \\
&= \frac{pb(1+L)/T}{1 - pb(1+L)/T}. \\
&= \frac{b \times ROE}{1 - b \times ROE}
\end{aligned}
\tag{64.16}
$$

Please note that, in the framework of internal growth rate and sustainable growth rate presented above, the source of cash are taken from the end of period values of assets and assumed that the required financing occurs at the end of the period. However, Ross et al. (2010) show that if the source of cash is from the beginning of the period, the relationship between the use and the source of cash can be expressed for the internal growth rate model as $\Delta ST = pSb$ and for the sustainable growth rate model, $\Delta ST = pbS + pbSL$. Such relationship will result an internal growth rate of $b \times ROA$ and a sustainable growth rate of $b \times ROE$. For example, Table 64.3 assumes identical assumptions to that of Table 64.1, but now we will assume a growth rate of 4.1667% and use total asset, total equity, and total debt from the beginning of the period balance sheet to calculate the net income. Recall that ROE is the net income divided by stockholders' equity at the beginning of the period. Note that the product of ROE and b will yield 4.1667%.

Note that the intent of the Higgins' sustainable growth rate allows only internal source and external debt financing. Chen et al. (2012) incorporate Higgins (1977) and Lee et al. (2011) frameworks, allowing company use both external debt and equity, and derive a generalized sustainable growth rate as

$$
g(t) = \frac{b \times ROE}{1 - b \times ROE} + \frac{\lambda \cdot \Delta n \cdot P/E}{1 - b \times ROE},
\tag{64.17}
$$

where

$$
\lambda = \text{ degree of market imperfection;}
$$

$$
\Delta n = \text{ number of shares of new equity issued;}
$$

$$
P = \text{ price per share of new equity;}
$$

and

$$
E = \text{total equity.}
$$

---

[5] Increased in Assets is the net increase in assets. The total investment should also include the depreciation expense as can be seen in our examples delineated in Tables 64.1 and 64.2. But depreciation expense is also a source of funding. Hence, it is netted out in the relationship between increases in assets and retained earnings and new borrowings.

Table 64.3 The book value of the firm's assets equal the market value of the firm (sustainable growth rate is 4.1667 %)

Comparing Equation 64.17, the generalized sustainable growth rate has an additional positive term, $\frac{\lambda \cdot \Delta n \cdot p / E}{1 - (1 - D)ROE}$, when the new equity issue is taken into account. Therefore, Chen et al. (2012) show that Higgins' (1977) sustainable growth rate is underestimated because of the omission of the source of the growth related to new equity issue.

64.4 Statistical Methods

Instead of relying on financial ratios to estimate firm's growth rates, one may use statistical methods to determine firm's growth rates. A simple growth rate can be estimated by calculating the percentage change in earnings over a time period, and taking the arithmetic average. For instance, the growth rate in earnings over one period can be expressed as:

$$g_t = \frac{E_t - E_{t-1}}{E_{t-1}}. \tag{64.18}$$

The arithmetic average is given by

$$\overline{g} = \frac{1}{n} \sum_{t=1}^{n} g_t. \tag{64.19}$$

A more accurate estimate can be obtained by solving for the compounded growth rate:

$$X_t = X_0 \, (1 + g)^t, \tag{64.20}$$

or

$$g = \left(\frac{X_t}{X_0}\right)^{1/t} - 1, \tag{64.21}$$

where

$X_0 =$ measure in the current period(measure can be sales, earnings, or dividends); and

$X_t =$ measure in period t.

This method is called the *discrete compound sum* method of growth-rate estimation. For this approach to be consistent with the dividend growth model, the duration of each period (e.g., quarterly or yearly) must be consistent with the compounding period used in the dividend growth model.

Another method of estimating the growth rate uses the continuous compounding process. The concept of continuous compounding process can be expressed mathematically as

$$X_t = X_0 e^{gt}. \tag{64.22}$$

Equation 64.21 describes a discrete compounding process and Equation 64.22 describes a continuous compounding process. The relationship between Equations 64.21 and 64.22 can be illustrated by using an intermediate expression such as:

$$X_t = X_0\left(1 + \frac{g}{m}\right)^{mt},$$ (64.23)

where m is the frequency of compounding in each year. If $m = 4$, Equation 64.23 implies a quarterly compounding process; if $m = 365$, it describes a daily process; and if m approaches infinity, it describes a continuous compounding process. Thus Equation 64.22 can be derived from Equation 64.23 based upon the definition

$$\lim_{m\to\infty}\left(1 + \frac{1}{m}\right)^m = e.$$ (64.24)

Then the continuous analog for Equation 64.20 can be rewritten as

$$\lim_{m\to\infty} X_t = \lim_{m\to\infty} X_0\left(1 + \frac{g}{m}\right)^{mt}$$
$$= X_0 \lim_{m\to\infty}\left(1 + \frac{1}{m/g}\right)^{\left(\frac{m}{g}\right)gt}.$$
$$= X_0 e^{gt}$$ (64.25)

Therefore, the growth rate estimated by continuous compound-sum method can be expressed by

$$g = \frac{1}{t}\ln\frac{X_t}{X_0}.$$ (64.26)

If you estimate the growth rate via Equation 64.26, you are implicitly assuming the dividends are growing continuously and therefore the dividend growth model. In this case, according to Gordon and Shapiro's (1956) model, $P_0 = d_0/(r - g)$.

To use all the information available to the security analysts, two regression equations can be employed. These equations can be derived from Equations 64.20 and 64.22 by taking the logarithm (ln) on both sides of equation:

$$\ln X_t = \ln X_0 + t\ln(1 + g).$$ (64.27)

If Equation 64.27 can be used to estimate the growth rate, then the antilog of the regression slope estimate would equal the growth rate. For the continuous compounding process,

$$\ln X_t = \ln X_0 + gt.$$ (64.28)

Table. 64.4 Dividend behavior of firms Pepsico and Wal-Martin dividends per share (DPS)

Year	T	PEP	WMT	Year	T	PEP	WMT
1981	1	3.61	1.73	1996	16	0.72	1.33
1982	2	2.4	2.5	1997	17	0.98	1.56
1983	3	3.01	1.82	1998	18	1.35	1.98
1984	4	2.19	1.4	1999	19	1.4	1.25
1985	5	4.51	1.91	2000	20	1.51	1.41
1986	6	1.75	1.16	2001	21	1.51	1.49
1987	7	2.30	1.59	2002	22	1.89	1.81
1988	8	2.90	1.11	2003	23	2.07	2.03
1989	9	3.40	1.48	2004	24	2.45	2.41
1990	10	1.37	1.9	2005	25	2.43	2.68
1991	11	1.35	1.14	2006	26	3.42	2.92
1992	12	1.61	1.4	2007	27	3.48	3.17
1993	13	1.96	1.74	2008	28	3.26	3.36
1994	14	2.22	1.02	2009	29	3.81	3.73
1995	15	2.00	1.17	2010	30	3.97	4.2

Both Equations 64.27 and 64.28 indicate that X_n is linearly related to t; and the growth rate can be estimated by the ordinary least square (OLS) regression. For example, growth rates for EPS and DPS can be obtained from an OLS regression by using

$$\ln\left(\frac{EPS_t}{EPS_0}\right) = a_0 + a_1 T + \varepsilon_{1t}, \text{ and}$$ (64.29)

$$\ln\left(\frac{DPS_t}{DPS_0}\right) = b_0 + b_1 T + \varepsilon_{2t},$$ (64.30)

where EPS_t and DPS_t are earnings per share and dividends per share, respectively, in period t, and T is the time indicators (i.e., $T = 1, 2, \ldots, n$). We denote $\hat{a}_1$ and $\hat{b}_1$ as the estimated coefficients for Equations 64.29 and 64.30. The estimated growth rates for EPS and DPS, therefore, are $\exp(\hat{a}_1) - 1$ and $\exp(\hat{b}_1) - 1$ in terms of discrete compounding process and $\hat{a}_1$ and $\hat{b}_1$ in terms of continuous compounding process.[6]

Table 64.4 provides dividends per share of Pepsico and Wal-Mart during the period from 1981 to 2010. Using the data in Table 64.4 for companies Pepsico and Wal-Mart, we can estimate the growth rates for their respective dividend streams. Table 64.5 presents the estimated the growth rates for Pepsico and Wal-Mart by arithmetic average method, geometric average method, compound-sum method, and the regression method in terms of discrete and continuous

[6] If the earnings (or dividend) process follows Equation 64.27, we can get same results from the non-restricted model as Equations 64.29 and 64.30.

Table 64.5 Estimated dividend growth rates for Pepsico and Wal-Mart

	Pepsico (%)	Wal-Mart (%)
Arithmetic average	4.64	8.99
Geometric average	0.99	5.45
Compound-sum method	0.99	5.30
Regression method (continuous)	0.56	7.04
Regression method (discrete)	0.56	7.29

$$\ln\left(\frac{DPS_t}{DPS_0}\right) = -0.6236 + 0.1947\ T + \varepsilon_t$$
$$\phantom{\ln\left(\frac{DPS_t}{DPS_0}\right) =} (0.0056)\quad (0.0113)$$

$$\ln\left(\frac{DPS_t}{DPS_0}\right) = -0.9900 + 0.0704\ T + \varepsilon_t$$
$$\phantom{\ln\left(\frac{DPS_t}{DPS_0}\right) =} (0.1286)\quad (0.0075)$$

Fig. 64.1 Regression models for Pepsico and Wal-Mart

compounding processes. Graphs of the regression equations for Pepsico and Wal-Mart are shown in Figure 64.1.

The slope of the regression for Pepsico shows an estimated coefficient for the intercept is 0.56. The estimated intercept for Wal-Mart is 7.04. The estimated growth rates for Pepsico and Wal-Mart, therefore, are 0.56% and 7.29% in terms of discrete compounding process. Figure 64.1 also shows the true DPS and predicted DPS for Pepsico and Wal-Mart. We find that the regression method, to some extent, can estimate the growth rate for Wal-Mart more precisely

Table 64.6 Estimated dividend growth rates for 50 randomly selected companies

	50 firms (%)	Firms with positive growth (35 firms) (%)	Firms with negative growth (15 firms) (%)
Arithmetic average	4.95	7.27	−0.47
Geometric average	0.93	3.00	−3.88
Compound-sum method	0.83	2.91	−4.02
Regression method (continuous)	0.66	2.32	−3.22
Regression method (discrete)	0.71	2.37	−3.15

than for Pepsico. Comparing to the geometric average method, the regression method yields a similar value of the estimated growth rate for Wal-Mart, while not for Pepsico.

There are some complications to be aware of when employing the arithmetic average, the geometric average, and regression model in estimating the growth rate. The arithmetic average is quite sensitive to extreme values. The arithmetic average, therefore, has an upward bias that increases directly with the variability of the data. Consider the following situation. Dividends in years 1,2 and 3 are $2, $4 and $2. The arithmetic average of growth rate is 25% but the true growth rate is 0%. The difference in the two average techniques will be greater when the variability of the data is larger. Therefore, it is not surprising that we find differences in the estimated growth rates using arithmetic average and geometric average methods for Pepsico and Wal-Mart in Table 64.5.

The regression method uses more available information than the geometric average, discrete compounding and continuous compounding methods in that it takes into account the observed growth rates between the first and last period of the sample. A null hypothesis test can be used to determine whether the growth rate obtained from the regression method is statistically significantly different from zero or not. However, logarithms cannot be taken with zero or negative numbers. Under this circumstance the arithmetic average will be a better alternative.

We further randomly select 50 companies from S&P 500 index firms, which paid dividends during 1981–2010, to estimate their dividend growth rates by arithmetic average method, geometric average method, compound-sum method, and the regression method in terms of discrete and continuous compounding processes. Table 64.6 shows averages of estimated dividend growth rates for 50 random companies by different methods. As we discussed before, the arithmetic average is sensitive to extreme values and has an upward bias. We, therefore, find a larger average of the

estimated dividend growth rate using the arithmetic average method. We also find that on average, the geometric, and compound sum methods yield relatively smaller growth rate estimates as compared to the estimates obtained using the regression methods to estimate growth rate. However, it appears that estimates obtained using the geometric, compound sum and regression methods are very similar.

Finally, Gordon and Gordon (1997) suggest that one can infer the growth rate using the dividend growth model. In particular, the practitioner can use regression analysis to calculate the beta of the stock and use the *CAPM* to estimate the cost of equity. Since

$$P_0 = \frac{d_0(1 + g)}{(r - g)} \qquad (64.31)$$

and the price of the stock is given by the market, the cost of equity is obtained using the *CAPM*, and d_0 and the current dividend is known, one can infer the growth rate using Equation 64.31. If the inferred growth rate is less than the practitioner's estimate, then the recommendation will be to buy the stock. On the other hand, if the inferred growth is greater than the practitioner's estimate, the recommendation will be to sell the stock. However, it should be noted that the explanatory power of the *CAPM* to explain the relationship between stock returns and risk has been extensively questioned in the literature. See for example, Fama and French (1992).

Conclusion

The most common valuation model is the dividend growth model. The growth rate is found by taking the product of the retention rate and the return on equity. What is less well understood are the basic assumptions of this model. In this paper, we demonstrate that the model makes strong assumptions regarding the financing mix of the firm. In addition, we discuss several methods suggested in the literature on estimating growth rates and analyze whether these approaches are consistent with the use of using a constant discount rate to evaluate the firm's assets and equity. In particular, we demonstrate that the underlying assumptions of the internal growth rate model (whereby no external funds are used to finance growth) are incompatible with the constant discount rate model of valuation. The literature has also suggested estimating growth rate by using the average percentage change method, compound-sum method, and/or regression methods. We demonstrate that the average percentage change is very sensitive to extreme observations. Moreover, on average, the regression method yields similar but somewhat smaller estimates of the growth rate compared to the compound-sum method. We also discussed the inferred

method suggested by Gordon and Gordon (1997) to estimate the growth rate. Advantages, disadvantages, and the interrelationship among these estimation methods are also discussed in detail. Choosing an appropriate method to estimate firm's growth rate can yield a more precise estimation and be helpful for the security analysis and valuation. However, all of these methods use historical information to obtain growth estimates. To the extent that the future may differ from the past, will ultimately determine the efficacy of any of these methods.

A Comparison of Formulas to Compute Implied Standard Deviation

65

James S. Ang, Gwoduan David Jou, and Tsong-Yue Lai

Abstract

We derive an exact closed-form solution for the implied standard deviation in the Black and Scholes' option pricing model under the condition that the underlying asset price equals the present value of the exercise price. The exact closed-form solution provides the true implied standard deviation and has no estimation error. We then relax this condition and develop three new formulas that depend on a Taylor series expansion utilizing one, two or three options. Simulations show these formulas produce lower estimation errors than extant approaches, and the third formula gives the best overall results under different parameter values.

Keywords

Implied standard deviation • Implied volatility • Options • Option pricing model • Taylor formula

65.1 Introduction

Standard deviation of the underlying asset return plays two roles: to estimate the option pricing and to capture the volatility of the underlying asset in the spot market. In Merton (1973) and Black-Scholes (1973) option pricing model, the standard deviation of the underlying asset's rate of return is the only parameter, which cannot be observed directly. How

to estimate an accurate standard deviation becomes a primary concern in option pricing and trading. Three approaches have been developed in the finance literature to estimate standard deviation: (1) the historical standard deviation, (2) the implied standard deviation (ISD) derived from equating the Black-Scholes' option pricing model with the market value of the call option, and (3) the multiple implied standard deviations from options with different exercise prices. Garman and Klass (1980) study the historical standard deviation by using open, high, low prices, and closed prices' data to estimate the standard deviation. To support the use of historical standard deviation for implied standard deviation in option pricing model requires that the underlying asset's rate of return is stationary over the option's life, which contradicts the time-varying standard deviation documented by Schwert (1989).

Implied standard deviation has been studied by Latane and Rendleman (1976), Beckers (1981), Manaster and Koehler (1982), Brenner and Subrahmanyam (1988), Lai et al. (1992), Chance (1996), Hallerback (2004), Corrado and Miller (1996, 2004), and Li (2005). Since the Black-Scholes' option pricing model is a nonlinear equation, an explicit analytic solution for the ISD is not available in the literature (except for at-the-money call) and numerical

methods are used to approximate the ISD. By applying the Newton-Raphson method, Manaster and Koehler (1982) provide an iterative algorithm for the ISD. Brenner and Subrahmanyam (1988) applied Taylor series expansion at zero base to the cumulative normal function in pricing Black-Scholes option pricing model up to the first-order term and set the underlying asset price to equal the present value of exercise price to solve the ISD. Following the same approach as Brenner and Subrahmanyam, Li (2005) expands the expression to third order term and solve for the ISD with a cubic equation. The accuracy of ISD derived by Brenner and Subrahmanyam (1988) and Li (2005) depends not only on the deviation of stock price (S) from the present value (K) of exercise price (E), but also on the magnitude of the ISD. Since Li includes third order term in the Taylor expansion on the cumulative normal distribution in his derivation, Li claims that his formula of ISD provides a consistently more accurate estimate of the true ISD than that of Brenner and Subrahmanyam's formula. It is worthy to note that both formulas are approximate rather than exact closed-form solution for ISD. Therefore, there exists certain amount of estimation error by using either formulas to test the ISD. Lai et al. (1992) derive a closed form solution for the ISD in terms of the delta $\partial C/\partial S$ and $\partial C/\partial E$. Given $C = S(\partial C/\partial S) + E(\partial C/\partial E)$, their closed-form solution can be simplified to depend on either $\partial C/\partial S$ or $\partial C/\partial E$ only.

To allow for the deviation between the underlying asset price and the present value of exercise price, Corrado and Miller (1996) follow Brenner and Subrahmanyam's approach by expanding the cumulative normal function at zero to the first order term to derive a quadratic equation of the ISD. The ISD is then obtained by solving the quadratic equation. However, to improve accuracy, Corrado and Miller made two substantial substitutions in their model.[1] First, ln(S/K) is replaced by 2(S − K)/(S + K). Second, 4 [(S − K)/(S + K)]^2 is replaced by α [(S − K)/(S + K)]^2 that minimizes the concavity at S = K. The accuracy of their improved formula depends on the accuracy of these substitutions. Hallerback (2004) also derives an improved formula, which is similar to Corrado and Miller's formula (1996), to compute the ISD. Corrado and Miller (2004) argue that the formula derived by Hallerback (2004) collapse to their formula if (1) the geometric mean (i.e., $\sqrt{SK}$) of the stock price and the present value of exercise price K in Hallerback's formula is substituted by the arithmetic mean (i.e., (S + K)/2), and (2) the parameter value of 1.85 in Hallerback's formula is substituted by the tweaking parameter α in Corrado and Miller's (2004) formula. However, this argument is questionable because the arithmetic mean is never less than the geometric mean. Li (2005) follows

Corrado and Miller's (1996) approach by expanding the Black-Scholes option pricing at the K/S to the third order. Li derives a formula of ISD which is slightly different from that of Corrado and Miller due to an extra term. However, Li acknowledges that the extra term in his formula could be ignored in most of the cases involving deep-in or out-of –the money options.[2]

Chance (1996) assumes different exercise prices result in different ISDs, which violates the constant variance assumption used in deriving the Black-Scholes' option pricing model. Under the existence of a call at-the-money assumption, Chance uses Brenner and Subrahmanyam's formula to calculate the at-the-money's ISD. Chance then applies Taylor series expansion to the difference of the call option (i.e., ΔC) in terms of the $\partial C/\partial S$, $\partial C/\partial E$, and the second order terms; all are calculated at-the-money. In order to apply Chance's formula[3] to compute the ISD, the standard deviation and the option price at-the-money must be given. In other words, if the underlying asset price deviates from the present value of the exercise price and the call option price is not available (or unobservable) in the market, then Chance's formula for the ISD may not apply.

In this paper,[4] we initially derive an exact closed-form solution for the ISD under the condition that the underlying asset price equals the present value of the exercise price. We relax this restrictive condition, and derive three alternate formulas to estimate the ISD. Applying Taylor series expansion on the Black-Scholes' option pricing model derives the first formula to estimate the ISD. The difference between this formula and previously derived formulas is that we apply Taylor's formula to the cumulative normal functions $N[ln(S/K)/(\sigma\sqrt{T})+\sigma\sqrt{T}]$ and $N[ln(S/K)/(\sigma\sqrt{T})-\sigma\sqrt{T}]$ at base $ln(S/K)/(\sigma\sqrt{T})$ up to the second-order terms[5] rather than at the zero point up to the first-order term. The deviation of this approach from the true cumulative normal value is of the magnitude $\pm\sigma\sqrt{T}$ rather than the larger $ln(S/K)/(\sigma\sqrt{T}) \pm \sigma\sqrt{T}$. The inclusion of the second-order terms can partially capture the non-linearity of the cumulative normal function and should improve the accuracy of the ISD. In sum, the advantages of this approach are to circumvent the ad hoc replacements present in CM and to improve the accuracy of the ISD's estimation.

---

[1] In detail see the Appendix.

[2] See Equation 65.15 and the footnote 3 in Li (2005). Li provides two formulas (65.10) and (65.16) for ISD, one is at-the-money and one is nearly at-the-money. Both formulas (65.10) and (65.16) in his paper include a term of $\cos[(\cos^{-1}(\sqrt{\pi}3\alpha/32))/3]$.
[3] Chance uses $\sigma = C^*\sqrt{2\pi}/(S\sqrt{T})$ in his formula, w here C* is the price of the at-the-money call.
[4] This paper extends the analysis in Ang et al. (2009).
[5] Although including the third (or higher) order in the Taylor expansion could improve the accuracy further but it would eliminate the applicability of the quadratic formula of ISD.

Under the Black-Scholes option pricing model, other thing being equal, different exercise prices result in different option values. Instead of using a single option to derive the ISD formula, this paper also explores multiple options with different exercises to derive the ISD formulas. Previous studies focus on a single option's expansion. The first term of the expansion is either at 0.5, if expands, at 0, or if, cumulative normal function, at $\pm \sigma\sqrt{T}$ and expands at-the-money. Unfortunately, $\pm \sigma\sqrt{T}$ is not known and therefore the first term of cumulative normal function at $\pm \sigma\sqrt{T}$ needs to expand further and inevitably results in some amount of truncation error due to the remaining terms in the Taylor expansion. In fact, as shown in Section 65.4, the error due to the first term in the expansion can be corrected if different exercises prices are used in the derivation. Given different exercises and the corresponding call option values, applying the Taylor expansion to the Black-Scholes pricing model on different exercise price produces a more accurate first term in the expansion than that in previous studies. Based on two call option prices for different exercise prices and on the Black-Scholes's model, we apply Taylor's formula to (1) both call option values, (2) the inverse cumulative normal functions. Ignoring the remainder terms of the Taylor's formula results in a quadratic equation of the ISD. Solving this equation produces the second formula to estimate the ISD. This formula can estimate the ISD for a wide range of the deviation between the underlying asset price and the exercise prices. Extending the same procedure to a third call option value, we derive the third formula to estimate the ISD.

The article is organized as follows. Section 65.2 presents an exact closed-form solution for the ISD if the underlying asset price equals the present value of the exercise price. Section 65.3 presents a formula for the ISD based on a single call option. Section 65.4 derives two formulas to estimate the ISD using two and three call options on the same underlying asset. Section 65.5 presents a simulation to compare the accuracy of the estimated ISD from different formulas. Section 65.6 summarizes our findings.

65.2 An Exact Closed-Form Solution for the Implied Standard Deviation: A Special Case

The call option pricing model derived by Black and Scholes (1973) and Merton (1973) is given by

$$
\begin{aligned}
C = S[&N(\ln(S/K)/(\sigma\sqrt{T}) + \sigma\sqrt{T}/2)] \\
&- K[N(\ln(S/K)/(\sigma\sqrt{T}) - \sigma\sqrt{T}/2)],
\end{aligned} \quad (65.1)
$$

where, C is the call premium, S is the underlying asset value, the present value of the exercise price K is equal to Ee^{-rT}. E is the exercise price, r is the instantaneous risk-free rate, T is the time to the maturity, σ is the standard deviation of the underlying asset rate of return on annual basis, and N(x) is the standard cumulative normal distribution function up to x.

Under the condition that the stock price equals the present value of the exercise price (i.e., $S=K=Ee^{-rT}$), Brenner and Subrahmanyam (1988) derive the following simple formula to compute the implied standard deviation.

$$
\sigma\sqrt{T} = \sqrt{2\pi}C/S. \quad (65.2)
$$

This formula is derived by applying Taylor series expansion at zero in the B/S model up to the first-order term, and the higher order terms are ignored. Since the higher order terms are omitted, Equation 65.2 is an approximation rather than an exact solution. The accuracy of the ISD calculated by Equation 65.2 depends not only on the deviation of the stock price S from the present value of exercise price K but also on the magnitude of the standard deviation $\tilde{\sigma}$.

However, when the underlying asset price equals the present value of the exercise price, the B/S model becomes[6]

$$
\begin{aligned}
C &= S[N(\sigma\sqrt{T}/2) - N(-\sigma\sqrt{T}/2)] \\
&= S[1 - 2N(-\sigma\sqrt{T}/2)] \\
&= S[2N(\sigma\sqrt{T}/2) - 1].
\end{aligned} \quad (65.3)
$$

Thus, an exact closed-form solution for the ISD[7] is

$$
\begin{aligned}
\sigma\sqrt{T} &= -2N^{-1}[(S-C)/(2S)] \\
&= 2N^{-1}[(S+C)/(2S)].
\end{aligned} \quad (65.4)
$$

Since the cumulative normal distribution is a monotonic increasing function, its inverse cumulative normal functions in Equation 65.4 must exist and be unique. Therefore, Equation 65.4 must be an exact and unique closed-form solution for the ISD if the present value of the exercise price equals the underlying asset price. It is noteworthy that the Taylor expansion plays no role in deriving Equation 65.4 and there is no truncation of the remainder terms. Hence, when the assumption $S=K=Ee^{-rT}$ holds, using Equation 65.4 to calculate the ISD results in the true ISD and as there is no estimation error. Previous formulas are approximate because they are derived by truncating the remainder terms in the

---

[6] Note that $N(-\sigma\sqrt{T}/2) = 1 - N(\sigma\sqrt{T}/2)$.

[7] Given S=K, the BS model becomes $C = S[N(\sigma\sqrt{T}/2) - N(-\sigma\sqrt{T}/2)] = S[N(\sigma\sqrt{T}/2) - (1 - (N(\sigma\sqrt{T}/2))] = -S + 2 SN(\sigma\sqrt{T}/2)$, solve the ISD yields Equation 65.4.

Taylor formula. The estimate error always exists. Equation 65.4 is the best formula for ISD and dominates all other formulas if the S = K. Equation 65.4 is useful to calculate the exact ISD in this special case because the popularity of the Excel, in which the inverse standard cumulative normal function is imbedded.[8]

Given Equation 65.3, the sensitivity of the call option of the exercise price and the hedge ratio at the S = K are determined by

$$\partial C/\partial K = -N(-\sigma\sqrt{T}/2) = -1/2 + C/(2S), \quad (65.5)$$

$$\partial C/\partial S = N(\sigma\sqrt{T}/2) = 1/2 + C/(2S). \quad (65.6)$$

Equation 65.5 is the sensitivity of the call option value from the striking price at K = Ee^{-rT}=S Equation 65.6 is the hedge ratio (delta) at the underlying asset price S equals the present value K of exercise price. Equation 65.5 shows that the $\partial C/\partial K$ must be greater than $-1/2$, while Equation 65.6 demonstrates that the delta must be greater than 1/2. Equations 65.5 and 65.6 provide a closed-form and exact solutions for the $\partial C/\partial K$ and delta. Given the closed-form and exact solution of the ISD in Equation 65.4, it is possible to find all of the closed-form and exact solutions for all of the Greeks of options at S = K. The following theorem summarizes the results of Equations 65.4, 65.5, and 65.6.

Theorem *Under the Black and Scholes call option pricing model, if underlying asset price S equals to the present value K of exercise price, then there is an exact closed-form solution for the ISD and is given by Equation 65.4. Further, $\partial C/\partial K$ and the hedge ratio at S = K are given by Equations 65.5 and 65.6 respectively.*

65.3 An Implied Standard Deviation Formula Under a Single Call Option

This section derives a formula to estimate the ISD by applying the Taylor series expansion on a single call option. We show that the improved formula for ISD derived by Corrado and Miller (1996) can be improved further without any replacements. Applying Taylor formula to both cumulative normal distributions in Equation 65.1 at L = ln(S/K)/($\sigma\sqrt{T}$) yields

$$N(L + \sigma\sqrt{T}/2) = N(L) + N'(L)\sigma\sqrt{T}/2 + N''(L)$$
$$(\sigma\sqrt{T}/2)^2/2 + e_1 = N(L) + N'(L)(\sigma\sqrt{T}/2)$$
$$[1 - \ln(S/K)/4] + e_1 \quad (65.7)$$

and

$$N(L - \sigma\sqrt{T}/2) = N(L) - N'(L)\sigma\sqrt{T}/2 + N''(L)$$
$$(\sigma\sqrt{T}/2)^2/2 + e_2 = N(L) - N'(L)(\sigma\sqrt{T}/2)$$
$$(1 + \ln(S/K)/4) + e_2 \quad (65.8)$$

where, e_1 and e_2 are the remainder terms of the Taylor's formulas. Equations 65.7 and 65.8 are obtained by the fact that N''(x) = $-$ N'(x)x.

Given N(0) = 1/2, N'(0) = $1/C\sqrt{2\pi}/S$, N'''(0) = $-$N'(0), N''(0) = 0 = N''''(0). We apply the Taylor's formula to the N[ln(S/K)/($\sigma\sqrt{T}$)] and N'[ln(S/K)/($\sigma\sqrt{T}$)] in Equations 65.7 and 65.8 at 0

$$N(L) = N(0) + N'(0)(L) + N''(0)(L)^2/2 + e_3$$
$$= 1/2 + L/\sqrt{2\pi} + e_3 \quad (65.9)$$

$$N'(L) = N'(0) + +N''(0)(L) + N'''(0)(L)^2/2 + e_4$$
$$= 1/\sqrt{2\pi} - L^2/(2\sqrt{2\pi}) + e_4 \quad (65.10)$$

where e_3 and e_4 are the remainders of the Taylor's formulas. Substituting Equations 65.7, 65.8, 65.9, and 65.10 into Equation 65.1, dropping all of remainder terms, Equation 65.1 becomes

$$C = (S - K)/2 + L[(S - K)(1 + [\ln(S/K)/4]^2)$$
$$- \ln(S/K)(S + K)/4]/\sqrt{2\pi} + (\sigma\sqrt{T}/2)[S$$
$$+ K - \ln(S/K)(S - K)/4]/\sqrt{2\pi}. \quad (65.11)$$

Equation 65.11 is a quadratic equation of $\sigma\sqrt{T}$ and can be rewritten as

$$\sigma^2T[4(S + K) - (S - K)\ln(S/k)] - 4\sigma\sqrt{T}\sqrt{2\pi}(2C - S + K)$$
$$+ 8\ln(S/K)[(S - K)(1 + (\ln(S/K)/4)^2)$$
$$- (S + K)\ln(S/K)/4] = 0 \quad (65.12)$$

Solving $\sigma\sqrt{T}$ from Equation 65.12 yields

$$\sigma\sqrt{T} = [b \pm \sqrt{b^2 - ac}]/a \quad (65.13)$$

---

[8] The function used to calculate the inverse cumulative normal function is named as "NORMSINV" in f_x of the Excel.

Where $a = 4(S+K)-(S-K)\ln(S/K)$, $b = 2\sqrt{2\pi}(2C-S+K)$, $c = 8\ln(S/K)[(S-K)(1+(\ln(S/K)/4)^2) - (S+K)\ln(S/K)/4]$. A merit of Equation 65.13 is to circumvent the ad hoc substitution present in CM and improve the accuracy of the ISD's estimation.

Since Equations 65.9 and 65.10 are the Taylor series at the zero point and the remainder terms e_1 to e_4 in Equations 65.7, 65.8, 65.9, and 65.10 are omitted in deriving Equation 65.11, the ISD calculated by Equation 65.13 is not an exact formula. Therefore, the effectiveness of using Equation 65.13 to estimate the ISD depends on the deviation of the underlying asset price from the present value of exercise price. The merits of this formula are: (65.1) it is derived without arbitrary substitution (see Appendix) as Corrado and Miller (1996), and (65.2) it provides a more accurate estimate of ISD than that of Corrado and Miller. As shown in the figures in Section 65.5, the estimated ISD based upon Equation 65.13 is more accurate and dominates the formula provided by Corrado and Miller (1996). Section 65.5 addresses in detail the accuracy of the ISD calculated by Equation 65.13 and that of the improved formula derived by CM.

65.4   Formulas for Implied Standard Deviation Under Different Exercise Prices

In this section we derive two formulas to estimate the ISD from call options with different exercise price. The derived formulas can apply to a wide range of exercise prices that deviate from the underlying asset price. The advantage from using options with different exercise prices in this section is to obtain a no error's first term in the expansion, thus, gives more accurate formulas for ISD. The first term in Taylor expansion usually provides the major component of the true function, the remaining terms provide correction to adjust and approximate the true function. For example, if the call option value C_1 with exercise price E_1 is expanded at the exercise price E_2, the first term of the Taylor series expansion is the given option value C_2 on E_2. Similarly, the first term of the Taylor expansion on option value C_2 on E_2 at exercise price E_1 is C_1. Since both C_1 and C_2 are given, there is no need to expand the first terms again.

Consider two call options C_1 and C_2 on the same time to the maturity with prices of E_1 and E_2 (where $E_1 < E_2$), their present value are K_1, and K_2, respectively. Applying Taylor's expansion to Equation 65.1 at K_2 for C_1 and at K_1 for C_2 respectively yield,

$$C_1 = C_2 - N(\ln(S/K_2)/(\sigma\sqrt{T}) - \sigma\sqrt{T}/2)(K_1 - K_2) + \varepsilon_1,$$

$$(65.14)$$

$$C_2 = C_1 - N(\ln(S/K_1)/(\sigma\sqrt{T}) - \sigma\sqrt{T}/2)(K_2 - K_1) + \varepsilon_2.$$

$$(65.15)$$

Here ε_1 and ε_2 are the remainder terms of C_1 at K_2 and C_2 at K_1 from Equation 65.1. Dividing both sides of Equations 65.14 and 65.15 by (K_2-K_1) and simple manipulations produce the same left hand side of $(C_1-C_2)/(K_2-K_1)$. Then applying the inverse function of cumulative normal function on both sides and after using the Taylor's formula yields the following equations

$$N^{-1}[(C_1 - C_2)/(K_2 - K_1)]$$
$$= \ln(S/K_1)/(\sigma\sqrt{T}) - \sigma\sqrt{T}/2 + \eta_1, \qquad (65.16)$$

$$N^{-1}[(C_1 - C_2)/(K_2 - K_1)]$$
$$= \ln(S/K_2)/(\sigma\sqrt{T}) - \sigma\sqrt{T}/2 + \eta_2, \qquad (65.17)$$

where η_1 and η_2 are the remainder terms of Taylor's formulas derived from Equations 65.14 and 65.15 respectively. After dropping the remainder terms, ISD solved individually from either Equation 65.16 or 65.17 could be more volatile than that solved simultaneously with both equations. Combining Equations 65.16 and 65.17 could cause the effects of remainder term $(\eta_1 + \eta_2)$ to partially offset and thus, reduce their variability. Dropping the remainder term $(\eta_1 + \eta_2)$, a simple manipulation produces the following equation

$$(\sigma\sqrt{T})^2 + 2N^{-1}[(C_1 - C_2)/(K_2 - K_1)](\sigma\sqrt{T}) - \ln[S^2/(K_1K_2)] = 0. \qquad (65.18)$$

Equation 65.18 is a quadratic equation of the ISD and thus can be solved as,

$$\sigma\sqrt{T} = -N^{-1}[(C_1 - C_2)/(K_2 - K_1)]$$
$$\pm \sqrt{[N^{-1}((C_1 - C_2)/(K_2 - K_1))]^2 + \ln(S^2/K_1K_2)}.$$

$$(65.19)$$

There are two solutions for the ISD in Equation 65.18, yet the ISD must only take one of them. It is clear that, if $(C_1-C_2)/(K_2-K_1) > 1/2$, the inverse of cumulative normal function on it must be non-negative. Consequently, ISD must take the value with the positive sign in Equation 65.19, or else ISD will become a negative, which violates the positive requirement for ISD. On the other hand, if $(C_1-C_2)/(K_2-K_1) < 1/2$ and $K_1<S<K_2$, the ISD must take the positive sign in Equation 65.19 too. The negative sign only apply when S is less than K_1. It is clear that if stock

price is less than the lower exercise K_1 (i.e., then both call options are out-of-the-money) and if we had chosen the value with the plus sign in Equation 65.19, ISD calculated by Equation 65.19 will be overstated.

Furthermore, if K_2 approaches K_1, then $(C_1-C_2)/(K_2-K_1)$ in Equation 65.19 tends to $-\partial C/\partial K$ and $\ln(S^2/K_1K_2)$ tends to zero. Given positive ISD, ISD calculated by Equation 65.19 must converge to $-2N^{-1}(-\partial C/\partial K)$ (see Equation 65.5). Convergence implies that the ISD in Equation 65.19 must take the negative sign for the exercise prices. Note that the ISD in Equation 65.19 is not an exact solution because the remainder terms η_1 and η_2 were dropped out in the derivation of Equation 65.18.

Equation 65.19 provides a formula to calculate the ISD. All of the parameters on the right hand sides of Equation 65.19 are given. A merit of this formula is that a sufficient condition to calculate ISD by Equation 65.19 only requires that there existed any two consecutive call option values with different exercise prices. Although it may not always hold that the call option value at S=K, it is easier to obtain any consecutive two traded call option values and their exercise prices in practice. In particular, Equation 65.19 is applicable to a wide range of exercise prices if their call options are observable. Of course, its accuracy will depend on the magnitude of the deviation between these two exercise prices. The closer are these two exercise prices, the lower is the remainder of the Taylor Formulas in Equations 65.14 and 65.15. Consequently, the ISD estimated by Equation 65.19 is more accurate than in previous models. In particular, both formulas by Corrado and Miller (1996) and by Li (2005) are only valid when calculated at near at-the-money. Outside this range, both formulas' performance is poor if not applicable.

Similar to Equation 65.18, if there is a third call option C_3 with the discounted exercise price K_3, then the following Equation 65.20 must hold for K_2, K_3 and C_2, C_3.

$$(\sigma\sqrt{T})^2 + 2N^{-1}[(C_2-C_3)/(K_3-K_2)](\sigma\sqrt{T}) \\ - \ln[S^2/(K_2K_3)] \\ = 0. \quad (65.20)$$

Given the constant variance assumption in Black and Scholes option model, the following Equation 65.21 is thus derived by subtracting Equations 65.20 from 65.18.

$$\sigma\sqrt{T} = \ln(K_3/K_1)/[2(N^{-1}((C_1-C_2)/(K_2-K_1)) - N^{-1}((C_2-C_3)/(K_3-K_2)))]. \quad (65.21)$$

An advantage of using Equation 65.21 rather than Equation 65.19 to estimate the ISD is to circumvent the sign issue

that appears in Equation 65.19. However, a drawback of using Equation 65.21 is that there must exist at least three instead of two call options for Equation 65.19. Equation 65.21 provide a simple formula to calculate ISD because all options values and exercises price are given and the inverse function of the standard cumulative normal function also available in the Excel spreadsheet. Instead of calculating a complex function of cosine and inverse cosine function in the formula in Li (2005), Equation 65.19 provides a more convenient approach to calculate ISD./Furthermore, the Li's formula suffers from limited applicable range as stated before. The accuracy of the ISD calculated by Equations 65.19 and 65.21 will be addressed in Section 65.5.

65.5 Accuracy of the ISD Models: Simulation Results

This section uses simulation to compare the accuracy of the estimated ISDs by different formulas. To conduct the simulations, we assume the following parameter values: the underlying asset price (S) is $100, continuous annual risk-free rate (r) is 6%, time to maturity (T) is at: 1 month, 3 months, 1 year and 2 year, and the constant standard deviation σ is to vary from:10%, 20%, 50%, 75%, and 80%. Under these assumptions, we use the Black and Scholes' option model, Equation 65.1 to calculate the theoretical call option values for different exercise prices. Finally, given the theoretical call option value and the assumed risk-free rate, underlying asset price, time to the maturity, and the exercise prices, we calculate the ISD from different formulas. We then compare the true ISD and the calculated ISD to gauge the accuracy of the formulas for the ISD.

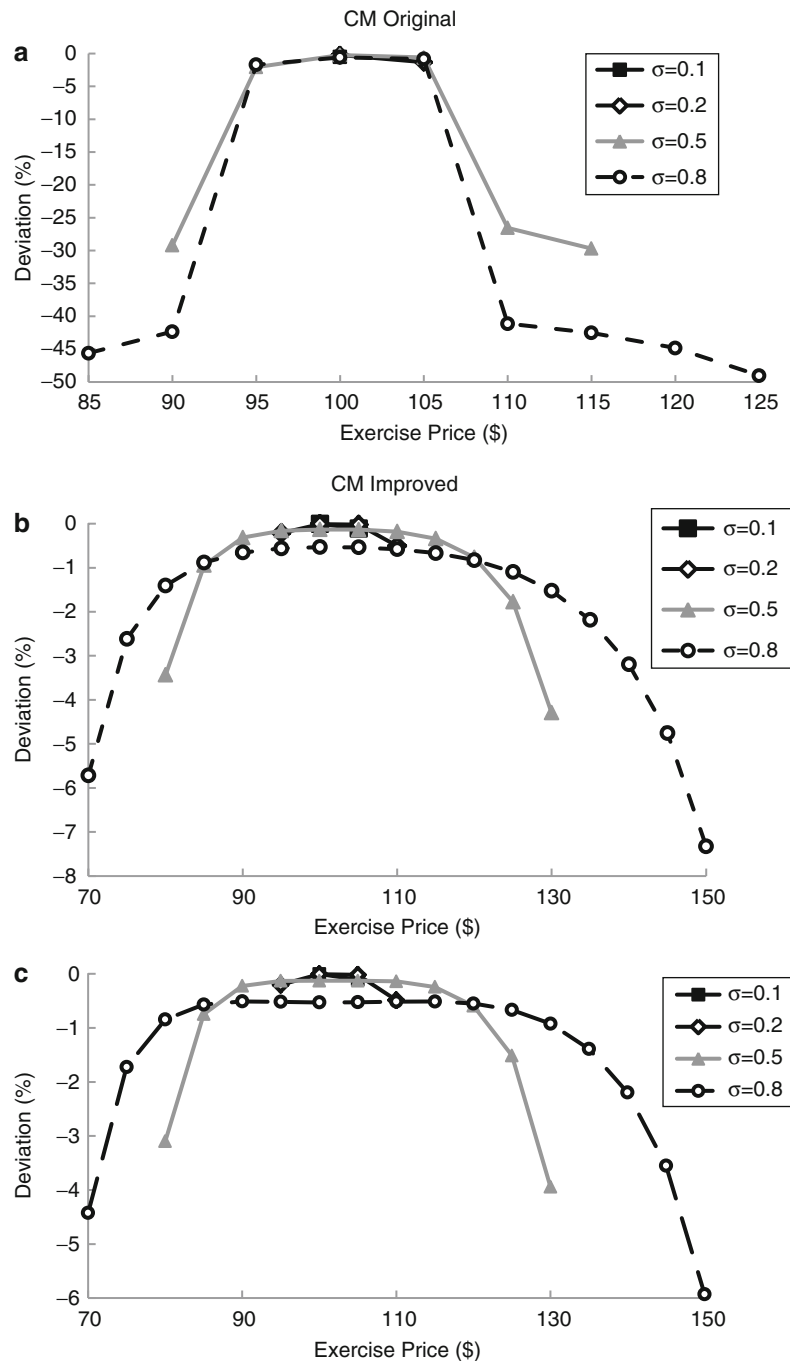
We start with comparing our three formulas (using one, two, and three options) with Corrado and Miller's two formulas (original and improved) for options with 3 months maturity. In Figure 65.1, we estimate the implied standard deviations using the parameters above. From these implied standard deviations, we calculate percentage estimation errors. Figure 65.1a, b plot the estimation errors of the two Corrado and Miller (CM) formulas under different asset prices with respect to exercise price of $100, i.e., moneyness of the options. We find the original CM has limited range of applicability: (a) It does not produce a positive ISD for options with small true standard deviations, or (b) for options that are far out or in the money. More serious is the rather large estimation errors that could be as large as 30–50% in underestimation. The improved CM manages to reduce underestimation error by several orders of magnitude, but nevertheless still suffer from limited range of applicability.


Fig. 65.1 A comparison of various formula to compute implied standard deviation: simulation results for 3 month options under different true standard deviation and moneyness (distance between current and exercise price). The parameters are: the underlying asset price (S) is $100, continuous annual risk-free rate (r) is 6%, time to maturity (T) is at: 1 month, 3 months, 1 year and 2 year, and the constant standard deviation σ is to vary from: 10%, 20%, 50%, and 80%. (**a**) ISD is calculated from Corrado Miller (CM, 1996): The Y axis gives the prediction error as estimated ISD minus true ISD divided by true ISD, and X axis gives the distance of exercise price from market price at $100. (**b**) ISD calculated from the improved version of Corrado and Miller (2004). (**c**) ISD calculated from Equation 65.13. (**d**) ISD calculated from Equation 65.19. (**e**) ISD calculated from Equation 65.21
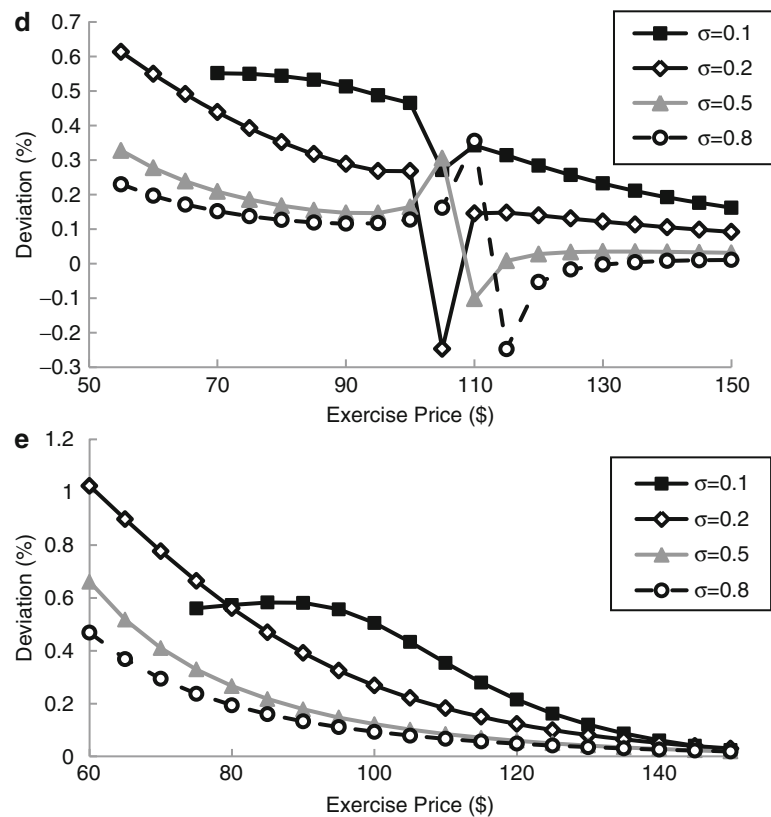

Fig. 65.1 (continued)

On the other hand our formula, using a single option (Equation 65.13, Figure 65.1c), manage to produce accurate estimates for some options with small standard deviations.

By adding one more option, (Equation 65.19, Figure 65.1d), not only is applicable to all options, the estimated ISDs reduce absolute estimation errors by several order of magnitude.

However, Equation 65.19 produces both positive and negative estimation error (over and under estimate), and there are kinks in the error functions for options in the neighborhood of the exercise price. Fortunately, this problem is solvable as demonstrated in the error functions for Equation 65.21, Figure 65.1e, with three options. We find these functions are well behaved for a wide range of moneyness of the options. Although ISDs calculated from Equation 65.21 tend to overestimate true standard deviation, the estimation errors are extremely small, only fraction of a percent. Furthermore, it has the widest range of applicability to options with different standard deviations. The accuracy of this formula, although ready high, improves as the price of the underlying asset increases, i.e., high accuracy for out of money options but extremely accurate for deep in the money options.

We also compare the estimation errors of these formulas under shorter maturity, 1 month (Figure 65.2a–c), and longer maturity of 1 year (Figure 65.3a–e). We find that discussions above generally hold: (a) CM still suffers from very large estimation errors and rather limited range of applicability with respect to both moneyness and true standard deviations. (b) Equation 65.13 performs as well if not better than CM improved, but has the benefit of not having to make arbitrary substitutions. (c) Equation 65.19 makes a marked improvement especially for out of money options, however, it still has undesirable kinks for in the money options. (d) Equation 65.21 consistently delivers the best overall results, it produces estimation errors around 1% or less for out of money options, and practically negligible for out of money options for all values of standard deviations used in the simulations.

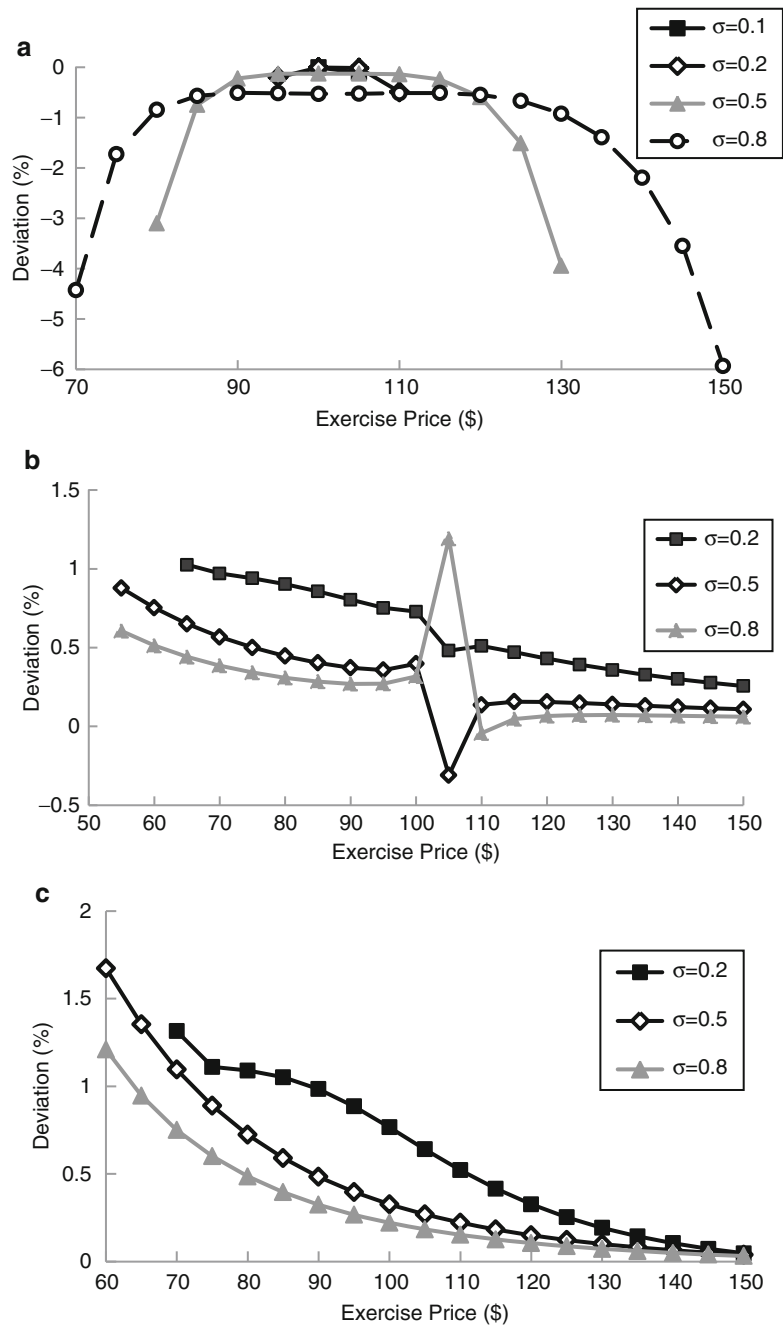
Finally, we examine the effect of maturity on estimation error. Here, we concentrate on Equation 65.2 as it is the best performing formula. We find that estimated ISDs under the formula (Figure 65.4a–c) improve with longer maturity, greater true standard deviation, and greater moneyness, i.e., more in the money options. For options with maturity over a year, estimated errors under Equation 65.21 at around a tenth of 1%, is for all purpose not of practical significance.


Fig. 65.2 A comparison of various formula to compute implied standard deviation: simulation results for 1 month options under different true standard deviation and moneyness (distance between current stock price and different exercise prices). Parameters same as in Figure 65.1. (**a**) ISD calculated from Equation 65.13. (**b**) ISD calculated from Equation 65.19. (**c**) ISD calculated from Equation 65.21

Conclusion

This paper derives an exact closed-form solution for the implied standard deviation under the condition that the underlying asset price equals the present value of the exercise price. Given this closed-form solution for the implied standard deviation, there are closed-form solutions for the delta (hedge ratio) and the other Greeks of the option.

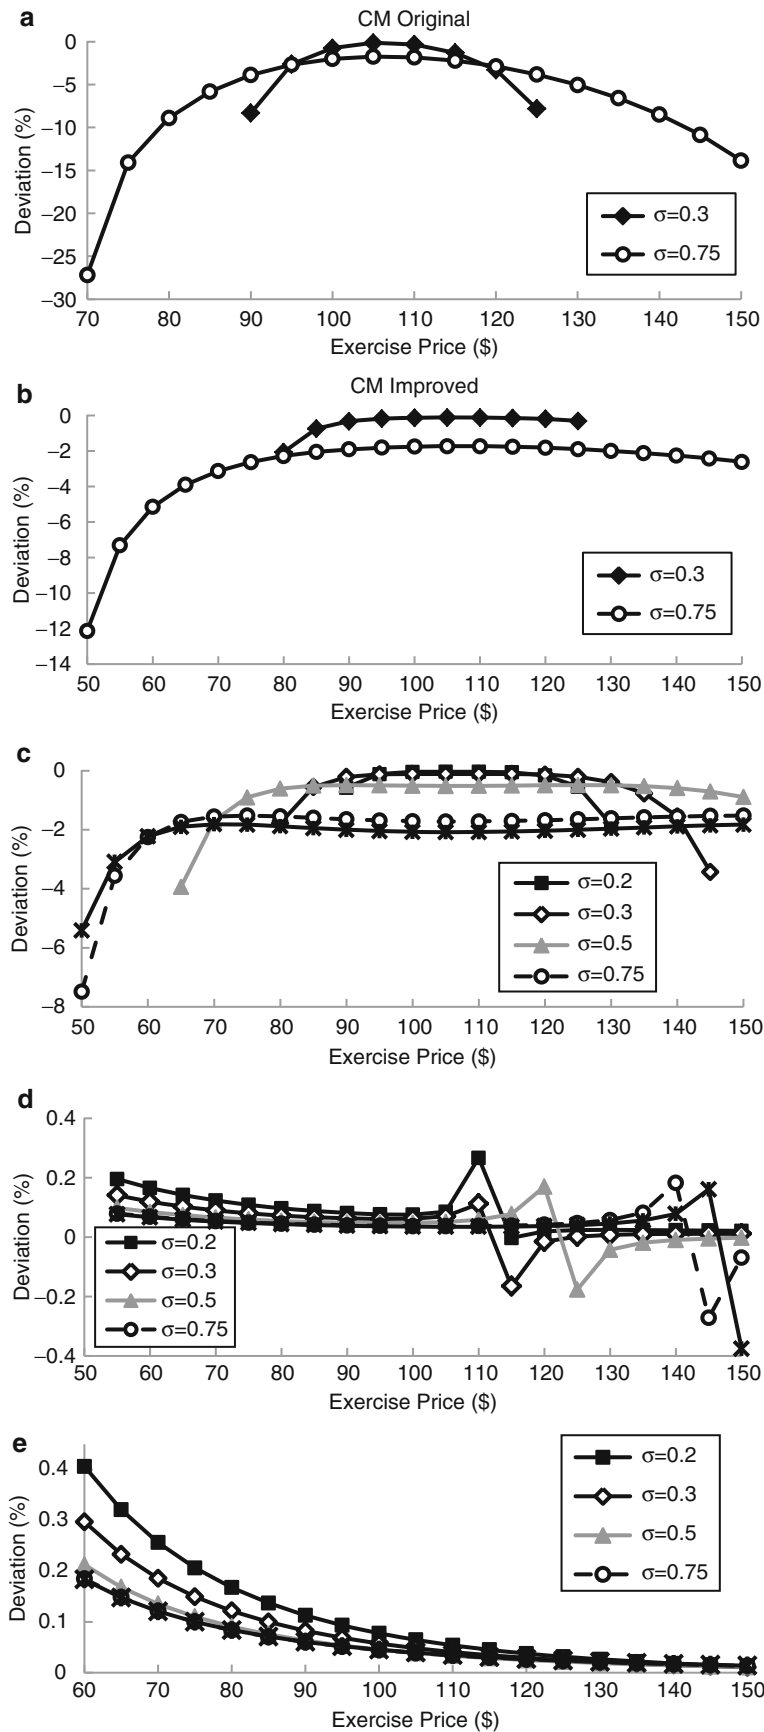
When we allow the underlying asset price to deviate from the present value of the exercise price, we derive three formulas to estimate the implied standard deviation. Applying the Taylor series expansion to the Black-


Fig. 65.3 Simulation results for 1 year maturity options. Parameters are the same as in Figure 65.1. (**a**) ISD calculated from Corrado Miller's original. (**b**) ISD calculated from Corrado and Miller Improved. (**c**) ISD calculated from Equation 65.13. (**d**) ISD calculated from Equation 65.19. (**e**) ISD calculated from Equation 65.21
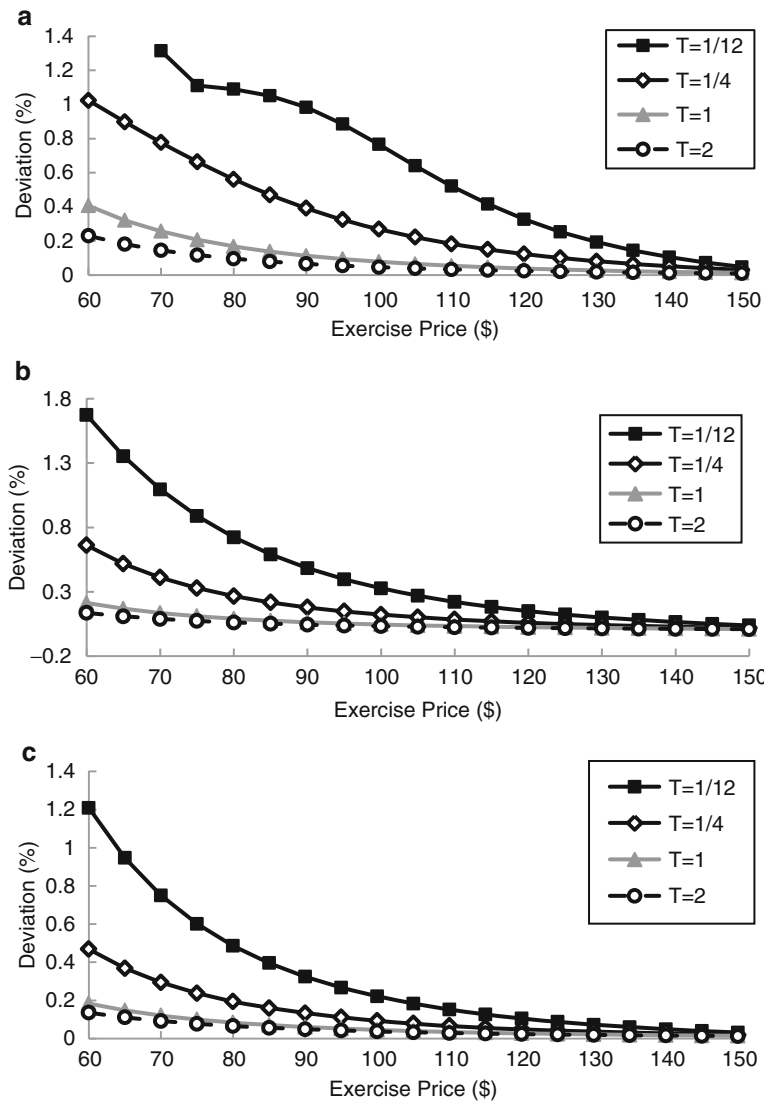

Fig. 65.4 The effect of maturity on estimation results: ISD estimated from Equation 65.21

Scholes option pricing model up to the second order, we derive the first formula to estimate the implied standard deviation. The ISD estimated by this formula is accurate for the near at-the-money call options. We then use two call options at different exercise prices to derive the second formula. This formula further improves the accuracy of the estimated ISD. We further extend this approach to include a third option to derive an even more accurate third formula. We show by simulation that this formula produce consistently accurate ISD for all parameter values in maturity, moneyness, and true standard deviations.

65.6 Appendix

Based upon Black and Scholes' option pricing model, Brenner and Subrahmanyam (1988) derive the following formulae of ISD under the condition that the stock price S equal to the present value K of the exercise price E:[9]

$$\sigma\sqrt{T} = \sqrt{2\pi}C/S \qquad (65.22)$$

Corrado and Miller (1996) expand the cumulative normal distribution in Black and Sholes model up to the third order

---

[9] This Appendix is suggested by an anonymous referee.

and omit the rest of reminders. The resulting Taylor expansion of option pricing model on the zero point results a quadratic equation of the ISD. They then solve for the ISD from the quadratic equation and derive the following formulae (65.23) of ISD (their Equation 65.6 in Corrado and Miller, 1996, detail see page 597).

$$\sigma\sqrt{T} = \sqrt{2\pi}[(C-(S-K)/2)/(S+K)]$$
$$+ \sqrt{2\pi[(C-(S-K)/2)/(S+K)]^2 - 2(S-K)\ln(S/K)/(S+K)}. \tag{65.23}$$

Corrado and Miller stated "The accuracy of the Equation 65.6 can be significantly improved by minimizing its concavity as follows. First, for simplicity only, we substitute the logarithmic approximation $\ln(S/X) \simeq 2(S-X)/(S+X)$ into Equation 65.6 and then replaced the value "4" with parameter α to obtain this restatement of the quadratic formula".

$$\sigma\sqrt{T} = \sqrt{2\pi}[(C-(S-K)/2)/(S+K)]$$
$$+ \sqrt{2\pi[(C-(S-K)/2)/(S+K)]^2 - \alpha[(S-K)/(S+K)]^2}. \tag{65.24}$$

This α is called tweaking parameter by Corrado and Miller (2004). To minimize the concavity of their Equation 65.7 (here the Equation 65.24 at the stock price equal to the present value X of exercise price, they derive a formula for α in terms normal density function and cumulate normal function with ISD. They solve the α (α is a function of unknown variable of ISD, detail see their Equations 65.8 and 65.9 in page 598) and then substitute $\alpha = 2$ to obtain the following formula of ISD Equation 65.25 (the Equation 65.10 in Corrado and Miller):

$$\sigma\sqrt{T} = \sqrt{2\pi}[C-(S-K)/2$$
$$+ \sqrt{(C-(S-K)/2)^2 - (S-K)^2/\pi}]/(S+K). \tag{65.25}$$

As shown by Corrado and Miller, their Equation 65.10 (here Equation 65.25) is more accurate than their Equation 65.6 (here Equation 65.23).

Securities Transaction Taxes: Literature and Key Issues

Anna Pomeranets

Abstract

The main scope of this chapter is to review the literature and key issues associated with securities transaction taxes (STTs). Despite the use of STTs around the globe, the theoretical and empirical literature on the impact an STT has on liquidity and volatility is mixed.

If an STT is not appropriately designed, it could interfere with the smooth functioning of financial markets, lead to informational inefficiency, arbitrage, tax evasion and double taxation. Effective implementation of STTs therefore requires cross-jurisdictional coordination, controls on cross-border transactions and carefully constructed enforcement.

Keywords

Tobin tax • Transaction costs • Transaction tax • Transfer tax • Volatility

66.1 Introduction

Financial markets are able to convert the underlying demands of investors into financial transactions. The imposition of a security transaction tax (STT), a tax on the purchase or sale of a financial security, affects this conversion. Proponents of STTs argue that such a tax, in addition to raising revenues for public services, may reduce excessive trading and market volatility because it creates a disincentive for short-term speculative trading by placing a financial burden on these transactions. On the other hand, because financial markets efficiently allocate resources in the economy, STTs reduce the ability of markets to do so and therefore reduce welfare. As past events have shown, STTs are not necessarily without risks and can have an unintended impact on financial markets.[1]

Despite the use of STTs around the globe, many aspects of their impact on financial markets are frequently debated by academics, politicians and policymakers.[2] In addition, the literature on the impact that an STT has on volatility and liquidity is inconclusive. This chapter reviews the existing literature and key issues associated with STT.

66.2 Theoretical Literature

Views on the impact STTs have on financial markets are divided. The earliest proponents of STTs, John Maynard Keynes and James Tobin, voiced the following rationale for the benefits of transaction taxes. First, the resources that financial markets require outweigh the role they play in economic welfare. The amount of capital that changes hands in financial markets exceeds the value of the fundamental transaction. Keynes (1936) contends that chasing short-term returns while potentially profitable, is a zero-sum game in terms of economic welfare. Because one investor's gain is another one's loss and trading utilizes resources, the value added through trading is negative. As a result, imposing an STT may increase welfare by

[2] STTs have been used in the U.S., U.K., Taiwan, Hong Kong and Sweden, among others. For more details see Matheson (2011).

reducing wasted resources. Second, because trading is speculative by nature, it potentially contributes to financial instability when trades are driven by short-term capital gains and not fundamental information. An STT could curtail short-term speculation, thereby reducing wasted resources, market volatility and asset mispricing. Finally, James Tobin in 1978 proposed a foreign exchange transaction tax to be levied globally in order to minimize cross-border capital flows that impair governments' efforts to control total demand. Thus, a tax on foreign exchange transactions would be a fiscal form of control that would make some cross-border dealings unprofitable, particularly in the short-term.

These original arguments were the grounds for many proposals and implementations of STTs around the world, and have ignited a long-lasting debate among academics, politicians and policymakers. This section reviews the literature around the impact an STTs has on volatility, liquidity and volume.

66.2.1 Volatility

Many advocates have furthered the debate in recent years, leading to an array of results. To date, there are three groups of papers that propose three contradicting theories on the impact an STT has on volatility.

The first group of papers, consistent with Keynes and Tobin, suggest that an STT will decrease volatility because it targets short-term noise traders. Stiglitz (1989) and Summers and Summers (1989) maintain that an STT would curb short-term speculation, thereby reducing exhausted resources, security mispricing and market volatility. Stiglitz (1989) theorizes that the tax targets short-term noise traders whose trades make markets more volatile. By using an STT to discourage noise traders from trading, volatility should be reduced. Similarly, Summers and Summers (1989) evaluate the costs and benefits of an STT. They suggest that excessive speculation increases volatility and conclude that the benefits of an STT outweigh its costs. Summers and Summers propose that the tax will reduce the activity of noise traders, resulting in the transaction price deviating less from the efficient price and thus causing a decrease in *excess* volatility and an increase in market quality.

Opponents of STTs focus on its potential to distort financial markets by reducing volume and liquidity, increasing price volatility and causing inefficient price discovery (see Amihud and Mendelson, 1992). They contend that an STT can lead to lower asset prices, increased cost of capital for businesses, lower returns to savings and widespread tax evasion. The second group of papers is consistent with the views of opponents and proposes an ambiguous impact of the tax on volatility because the tax will affect both informed

traders and noise traders. For example, Schwert and Seguin (1993) suggest that there is no evidence of *excess* volatility and since the tax is a burden on all traders, the reduction in trading will not limit the activity of noise traders alone—it will affect liquidity traders and price-stabilizing informed traders as well. They conclude that the STTs' impact on volatility is ambiguous and emphasize the unclear effect it would have on market quality.

The final portion of the theoretical literature concludes that an STT will have a direct effect on volatility because it reduces informed trading. Kupiec (1996) develops a model where an increase in the level of the STT increases excess volatility. Similarly, Amihud and Mendelson (2003) conclude that an STT results in an increase in volatility. They argue that transaction taxes reduce the amount of informed trading thereby widening the gap between the transaction price and the security's fundamental value. For example, when a price deviates from its value, informed traders buy it if the security is undervalued or sell it if it is overvalued; in so doing, the price moves back toward its fundamental value. Since informed traders incorporate transaction costs into their trading decisions, an STT will increase the costs faced by an informed trader and in turn result in larger deviations from fundamental value before profits are large enough to induce informed traders to trade. These larger deviations then result in an increase in volatility.

In summary, the existing theories on the impact an STT has on volatility are inconsistent and can be categorized into three groups. Consistent with advocates of the tax, the first group finds that an STT will result in a decline in volatility because it targets short-term noise traders. The second group contends that an STT will target all investors and therefore its impact on volatility will be ambiguous. The final group, consistent with opponents of an STT, argues that the tax will be accompanied by a rise in volatility. These contradictory theories feed the debate among proponents and opponents of an STT.

66.2.2 Liquidity and Volume

Consistent with the lack of consensus on the impact a securities transaction tax has on volatility, the theoretical literature on the relationship between an STT and liquidity is also inconclusive. Schwert and Seguin (1993) theorize that liquidity would be affected by an STT whereas Stiglitz (1989) theorizes that the impact would be insignificant. Importantly, these papers draw on the indirect effect of trading volume on liquidity to interpret the impact of an STT on liquidity.

Schwert and Seguin (1993) conceive that an STT would indirectly increase transaction costs through the three components of the bid-ask spread: order processing costs,

inventory risk and information asymmetry.[3] First, since an STT reduces trading volume, the number of trades available for the market-maker to recover his fixed cost declines, thereby increasing the order processing component of the spread. An STT will also increase the order processing component directly due to the cost of collecting the tax. Second, because equity market-makers use derivatives to hedge their risky inventory positions, an STT on derivatives increases the cost of hedging their positions. The increase in the market-maker's cost for hedging increases the inventory risk part of the bid-ask spread. Finally, if an STT reduces the amount of noise trading, as proponents suggest, then the possibility of the market-maker facing an informed trader increases, thereby increasing the information asymmetry element of the bid-ask spread. The authors theorize that an increase in spreads results in an increase in the cost to traders who take advantage of security mispricings, and thus reduces market efficiency. That is, when transaction costs increase, larger and more persistent mispricings are likely.

In contrast, Stiglitz (1989) argues that the impact of an STT would be insignificant by examining the inventory risk component of the bid-ask spread. He contends that although an STT will lead to thinner markets because the tax will discourage both buyers and sellers from trading, the change in liquidity will be insignificant. As markets become thinner, the time period between the entry of buy and sell orders widens. As a result, market-makers are forced to hold onto risky assets for longer, increasing the inventory risk component of the bid-ask spread. Despite the suggested increase in the bid-ask spread, Stiglitz argues that the impact of an STT on widely traded stocks will be insignificant as the extra minutes or seconds that market-makers hold onto the securities will not yield a significant change.

In summary, the theoretical arguments on the impact STTs have on volatility and liquidity are mixed and inferred from the inverse relationship that an STT has with volume. As a result, there have been numerous efforts to sort out the issues empirically. The next section reviews the findings in the empirical literature.

66.3   Empirical Literature

The empirical literature assesses three concerns of STTs: the impact the tax has on volatility, volume and liquidity. This section reviews the findings in the empirical studies around these measures of market quality.

66.3.1   Volatility

The tax is geared toward reducing the amount of speculative trading and thus stock market volatility. Proponents of the tax conjecture that the relationship between an STT and volatility is inverse. However, this proposed relationship is not observed in the empirical literature. Similar to the contradictory results in the theoretical literature on the impact of an STT on volatility, the empirical studies also provide varied results that can be divided into two clusters.

The first group finds a direct relationship between an STT and volatility and contradicts what advocates of the tax propose. Studies such as Umlauf (1993), Jones and Seguin (1997), Green et al. (2000), Hau (2006) and Baltagi et al. (2006) find a direct relationship between STTs and volatility. Umlauf (1993) looks at the Swedish Stock Market in the 1980s and finds that with an increase in an STT, volatility also increases. He finds that during the period with the highest STT rate, daily variances are at their highest levels as well. Jones and Seguin (1997) look at the repeal of fixed commissions on the NYSE and AMEX in 1975 and find that a decrease in commissions is accompanied by a decrease in volatility.[4] Green et al. (2000) examine the transfer tax in the UK and find that the tax and volatility are directly related. Hau (2006) looks at an increase in transaction costs in the French Stock Market as a result of tick size regulations and finds that as transaction costs increase, volatility also increases. Baltagi et al. (2006) find a significant increase in volatility following an increase in the tax policy from 0.3% to 0.5% in the Chinese Stock Market. These results are consistent with what opponents of the tax argue: an STT has adverse effects on volatility. It should be noted that Jones and Seguin and Hau study changes in transaction costs and not an actual change in the level of an STT. While the abolition of fixed commissions and a tick size change are pseudo-taxes because they are a onetime decrease in the transaction cost, they are not necessarily identical.

The second cluster of papers finds that volatility remains unchanged after a change in the level of an STT. This group of papers is also in stark contrast with what proponents of an STT surmise. For example, Pomeranets and Weaver (2011) examine nine changes in the level of a New York State imposed STT and find no consistent relationship between an STT and volatility. Roll (1989) examines stock return volatility for 23 countries that impose STTs and finds no evidence that volatility is related to transactions taxes. Similarly, Saporta and Kan (1997) find no relationship between the U.K. STT and price volatility, and Hu (1998) finds no reliable relationship between an STT and volatility for

---

[3] The order processing component is part of the fixed cost the market-maker charges for trade execution. The inventory risk component is the market-maker's compensation for holding onto risky assets. The information asymmetry component represents the likelihood that a market-maker is facing an informed trader who has superior knowledge of the asset's fundamental value.

[4] The abolition of fixed commissions is a pseudo-tax because it is a one-time decrease in the transaction costs on the New York and American Stock Exchanges.

changes in the level of an STT in Hong Kong, Japan, Korea, and Taiwan between 1975 and 1994. Bloomfield et al. (2009) create a laboratory market and find that price volatility is higher for periods when noise traders trade actively; however, after an STT is imposed, volatility is not significantly reduced despite the fact that noise traders submit fewer orders. Similarly, Sahu (2008) examines the imposition of an STT on the Indian Stock Market in 2004 and finds that an STT has no impact on volatility.

Both clusters of papers assessing the impact of an STT on volatility are in stark contrast with what advocates of the tax suggest: an STT will result in a decline in volatility. However, the literature does not support this conjecture.

66.3.2 Volume

There is a general consensus in the empirical literature that the relationship between a securities transaction tax and volume is inverse. Jones and Seguin (1997) and Baltagi et al. (2006) find an inverse relationship between volume and an STT. When an STT is imposed, some traders may stop trading. These results are consistent with the theoretical literature on the relationship between volume and a securities transaction tax.

In similar vein, when a transaction tax increases on one exchange, it drives volume to another exchange. Pomeranets and Weaver (2011) find that the New York Stock Exchange market share is inversely related to a New York State imposed STT. Campbell and Froot (1993) look at an STT for 20 different countries and find that an increase in the tax results in a loss of market share domestically and an increase in market share abroad. Umlauf (1993) finds that an increase in a securities transaction tax results in a decline in market share in the domestic country. These results are consistent with what opponents of the tax surmise. An STT drives trading to locations that do not impose an STT.

66.3.3 Liquidity

One main purpose of an organized financial market is to provide liquidity. A financial market should allow traders to buy and sell securities quickly and at low costs. Liquidity can be measured by the bid-ask spread, market depth, immediacy, price impact and resilience. The literature on the impact of stock transaction taxes on liquidity is limited.

Pomeranets and Weaver (2011) measure the impact of an STT on spreads and find an STT has a direct relationship with spread width. That is, imposing or increasing an STT is associated with a wider spread. Pomeranets and Weaver also examine price impact and find that an STT adversely affects market quality.

Bloomfield et al. (2009) study the relationship between liquidity and STTs in a laboratory setting in the context of different types of traders. If noise traders are less active because of the STT, the inventory risk component of the spread may decrease; the adverse selection cost may increase; or it may remain unchanged. If noise traders trade less, then prices will be less volatile and the inventory risk component of the bid-ask spread will decline, thereby increasing liquidity. However, if noise traders trade less, increasing the probability of informed trading, then the adverse selection costs could increase, resulting in a decline in liquidity. Finally, given a decline in noise trading from an STT, informed traders may trade less aggressively on their information, keeping adverse selection costs unchanged. Bloomfield et al. (2009) use the total price impact as a proxy for liquidity and find no significant impact on the bid-ask spread or price impact.

Empirical examinations face three chief obstacles. First, the effects of taxes on prices and volume are difficult to unravel from market structure and other policy changes that coincide with an STT. As a result, conclusions drawn on the assumption that everything except the STT change is constant are potentially biased. Second, it is hard to decouple transaction volume into stabilizing and destabilizing components. Thus, it is difficult to decipher which portion of the volume—noise or other—is more affected by the tax. Finally, it is difficult to distinguish between the various ways that STTs can affect security prices. These include adjustments in expectations about the impact of the taxes as well as changes in market liquidity. As a result, the general findings in the empirical literature are inconclusive.

66.4 Key Issues

There are several difficulties with the use, design and effectiveness of implementing STTs. If an STT is applied to one asset class, volume may migrate to an asset class without an STT. Habermeier and Kirilenko (2001) develop a model that shows how a stock transaction tax could decrease demand for stocks and increase demand for derivatives. Matheson (2011) argues that "taxing securities without taxing their derivatives could result in migration of trade from the spot markets to the derivatives markets, with an accompanying increase in leverage and risk." Therefore, in implementing an STT, the relationship between taxed and untaxed securities should be considered.

While taxing all financial instruments may appear to be the solution, this raises new obstacles. Taxing exchange-traded instruments would be relatively straightforward, but taxing over-the-counter transactions would be both expensive and difficult to implement. Therefore, the types of financial instruments that should be taxed needs considerations.

Further, evidence shows that if an STT is implemented in one jurisdiction and not another, volume will migrate. Pomeranets and Weaver (2011) and Umlauf (1993) show that an STT results in a decline in volume because traders

either move their activities to regions without and STT or stop trading entirely. The loss in trading volume may hinder the information efficiency of the financial market because volume contains informational content.

Furthermore, if a large portion of the trading volume shifts to a tax haven as a result of an STT, there will be less revenue collected than originally projected. Since advocates of STTs propose that the tax will raise substantial revenues, the transfer of volume will reduce the number of taxable transactions thereby reducing the potential revenues.

An additional concern with imposing an STT is territoriality. An STT can be applied to transactions based on the location of the trade, the location of the investor, or the location of the securities' issuer. Great care should be taken in defining territoriality policies and definitions as gaps may arise that result in tax evasion. Furthermore, cross-jurisdictional coordination needs to be developed to avoid double taxation. If one country uses residency criteria to tax transactions and another country uses the place of transaction, investors may be at risk of double taxation.

Introducing an STT warrants certain exemptions and limitations. Initial public offerings and transactions in the primary markets should be exempt from an STT. In addition, a limit should be imposed on the maximum tax liability for investors. This limit could be based on transaction volume or size and would reduce the tax burden for individual investors so that large investors would not be at a disadvantage.

If an STT is not appropriately designed it could interfere with the smooth functioning of financial markets, lead to informational inefficiency, arbitrage, tax evasion and double taxation. Therefore, effective implementation of STTs requires cross-jurisdictional coordination, controls on cross-border transactions and carefully constructed enforcement.

Conclusion

This chapter reviews the theoretical and empirical literature that studies the impact an STT has on financial markets, as well as some key issues associated with STTs. The theoretical arguments on the impact STTs have on market quality are mixed. Some theories predict a negative relationship between an STT and volatility and liquidity, and others point to a positive relationship. As a result, there have been numerous attempts to sort out the debate empirically. Generally, the empirical studies find that an STT is inversely related to volume and directly related to spreads. The literature also finds no significant relationship and in some cases a positive relationship between STTs and volatility. These findings are in stark contrast to what advocates of the tax propose since an STT can increase volatility, and reduce liquidity and the efficiency in financial markets. As a result, when implementing an STT, policymakers will need to consider ways to mitigate the unintended consequences of STTs.

Financial Control and Transfer Pricing

67

Savita A. Sahay

Abstract

This paper intends to explore transfer pricing and some popular transfer pricing methods. Since transfer prices are used to assess the incomes of the firm's divisions, choice of a transfer pricing policy can influence many important operational and strategic decisions, such as capital and resource allocation, volume and efficiency of production, performance evaluation as well as tax planning.

We use a descriptive method to study and compare the most popular transfer pricing policies used in American industry and find that many transfer pricing policies may lead to sub-optimal decisions and conflicts within the company because of the incentives they create for managers.

For the purpose of optimal decision making in a multi divisional form, Actual cost-based transfer pricing with an additive markup has been shown to dominate an entire class of alternative policies. In multinational corporations, there is an incentive to reduce the overall income tax burden by charging higher prices to units located in countries with high tax rates. This paper also explores the economic incentives for the use of a particular transfer pricing policy by multinational companies.

Keywords

Comparison • Divisional performance evaluation • Optimal • Popular methods • Tax planning • Transfer pricing

67.1 Introduction

In decentralized firms, a transfer price is usually assessed for internal transactions in which one division of the firm provides an intermediate product or service to another. The transfer price appears in the income statement of the selling division as part of its revenue, and in that of the buying division as part of its cost. Since managers are typically evaluated and compensated based on the reported income of their divisions,[1] the method used for setting transfer prices directly influences the decisions delegated to them. This makes transfer pricing policy (henceforth TP) an important tool in the hands of upper management for coordinating autonomous subordinate divisions. Additionally, the choice of TP policy is an important one for high-level management since TP is related to many other operational and strategic processes within the firm.[2]

---

[1] According to Merchant (1989, about 95 % of the US managers' compensation is based on their divisional income.

[2] These include tax planning, capital and other resource allocation, costing, decentralized co-ordination and control as well as performance evaluation, and formulation of integration and diversification policy.

While the choice of a transfer pricing policy is important and contentious, it is a fascinating and curious phenomenon. Activities within an organization are clearly non-market in nature- products and services are not bought and sold as they are in market transactions. Yet, establishing prices for transfers among subunits of an organization has a distinct market flavor. The rationale for transfer prices is that subunit managers, when evaluating decisions, need only focus on how their actions will affect subunit performance without worrying about their impact on companywide performance. In a well functioning transfer pricing system, optimizing subunit performance leads to optimizing the performance of the organization as a whole.

The Transfer Pricing (TP) problem becomes even more complex when a company has multiple divisions or subsidiaries operating in different countries that have different tax rates, tariff and import duties, currency and foreign exchange restrictions. In multinational corporations, there is an incentive to reduce the overall income tax burden by minimizing profits in the higher tax countries and maximizing profits where the tax rates are lower.

Since large multi divisional firms delegate many decisions to the divisional managers, designing a financial control systems that would coordinate the decisions throughout an organization and will guide the behavior of its employees is an important task. To be effective, financial control systems should reflect an organization's strategies and goals. Since an organization's major goal is to earn a satisfactory profit, the control systems put in place must ensure that the goals of the organization are consistent with the goals of its individual members (the goal congruence objective). Managers and other employees of the company are individuals who might have personal goals, often in contrast with organizational goal. For example, a company would prefer an employee to exert maximum effort towards achieving a goal, while the employee might prefer to work as little as necessary to keep his job. Management control systems must motivate managers and other employees to exert maximum effort through a variety of monetary (cash, company shares, vacations) and nonmonetary (promotion, pride in working for a successful company) rewards.

In this chapter, we will try to understand how a corporation's senior executives design and implement the financial control systems that are used to plan and control the firm's performance. Although there are many aspects of financial control, such as strategic planning, budgeting, performance measurement, responsibility center allocation and transfer pricing, we will restrict our attention to the two most important aspects of financial control:

1. Design of responsibility centers
2. Selection of an appropriate transfer pricing methodology.

67.2 Designing Responsibility Centers

A desirable feature of financial control systems is that they should be designed to reflect the decision-making responsibility of individual managers. This necessitates assigning financial responsibility (in terms of costs, revenues, profits and assets) to organization subunits. These subunits are called **Responsibility Centers** (RC). A responsibility center is an organization subunit that is headed by a manager who is responsible for its activities. Since the managers' compensation is often dependent on the financial performance of the division, managers are automatically motivated to maximize the difference between its inputs and outputs. Since a company is a collection of responsibility centers, if each center earns a satisfactory profit, the company as a whole will earn satisfactory profit, a major objective of any profit- oriented organization. In this sense, Financial Control measures how well a company or a RC or any department controls its cost and maximizes its profits.

The core operation of any RC involves receiving inputs in the form of material, labor and services, and transforming them into outputs, either tangible (i.e. goods) or intangible (i.e. services). The products produced by a RC may be transferred either to another RC, where they are inputs, or to the outside marketplace, where they are outputs of the organization, and earn a revenue. To measure their performance, the company may use one of the four types of RCs:

67.2.1 Cost Centers

A division is established as a cost center whenever central management can measure the output, knows the cost function and can set the appropriate quantity of output. Cost center managers are given the authority to determine the mix of inputs (Labor, materials and outside services) and they are evaluated based on their efficiency in applying inputs to produce outputs. Since they do not sell their product or services themselves, they are not evaluated on profits or revenues.

Cost centers are typically manufacturing departments which are asked to produce a quantity level determined by top management and are either responsible for minimizing cost for a given output or to maximize output for a given budget.

Since the cost center manager is typically evaluated based on minimizing costs, he has the incentive to lower the costs by lowering quality of inputs resulting in a possible reduction in the quality of the final part or output. Therefore the quality of products manufactured in a cost center must be carefully monitored.

In cases where cost center managers are allowed to choose the level of output, they have the incentive to choose

the output level at which the center's average costs are minimized, which may not be the optimal production level (Usually the level at which marginal costs are minimized) for the company's profits. Moreover, cost center managers have an incentive to over-report costs so that they can either pocket the slack or exert minimal effort in reducing costs.

Thus, cost centers are ideal for situations where the central management determines the output level, has a good idea of the division's cost function, can observe the quality of the output and can set the appropriate rewards.

67.2.2 Revenue Centers

In a revenue center, output is measured in monetary terms but the expenses are typically not matched with revenue. Revenue centers are usually marketing divisions that do not have the authority to set selling prices and are evaluated against target revenues or budgets. A center that is responsible for both expenses and revenues is called a profit center.

67.2.3 Profit Centers

Profit centers are divisions responsible for both the revenues and the costs and are typically evaluated based on their efficiency in applying inputs to produce outputs. Profit centers are set up when the knowledge required to make the product is firm specific, the internal decisions regarding quantity, quality and pricing of the output are proprietary information, costly to transfer outside the division.

Since profit center managers are responsible for maximizing the division's profits, rewarding them with a portion of their divisional income seems straightforward. However, there are a large number of profit centers that produce an intermediate product, to be transferred within the company. As we will see later, companies often use a Transfer Price to evaluate these transactions. The choice of an inappropriate transfer pricing method can lead to suboptimal quantity, quality or input mix decisions by the profit center manager.

A second problem arises when company's overhead costs are to be allocated to these business units. The allocation of corporate overhead costs is often arbitrary and is under constant debate because it reduces the total profit of the center.

As a result, profit maximization by an individual profit center may not maximize profits for the firm as a whole due to inter dependencies among different centers. For example, a profit center using resources to advertise its product might hurt the sales of another product by the same company, leading to overall lesser profit for the firm as a whole.

To help managers internalize the effect of their decisions on the company as a whole and other profit centers, profit center managers are often compensated based on their own as well as firm wide profits.

67.2.4 Investment Centers

Investment centers are similar to profit centers except that they have additional authority to take capital investment decisions. They are typically evaluated on measures such as return on investment or residual income. Investment centers are established when the manager has specific knowledge about investment opportunities and possesses information specific to the operating decisions. An investment center may have many profit centers and cost centers inside it.

67.2.4.1 Return on Investment (ROI)

Return on Investment (ROI) is used by a large majority of US firms as a method of compensating investment center managers. It is the ratio of operating net income divided by the total investment made in the center. The method has intuitive appeal because it compares the center's performance automatically with other centers and with other industry benchmarks.

However, ROI creates incentives for sub-optimal decision-making by the center manager, hurting the company's overall profit or quality or reputation or long term prosperity. For example, the manager may try to increase operating income by decreasing depreciation, research and development and other discretionary expenses. He may try to artificially increase the revenue (Hence inflate the income, the numerator in the equation) by a practice known as Channel Stuffing, in which managers will supply the product around the year-end to customers, even though they neither ordered nor need them.[3] This action may record additional revenue at the year end for the investment center, but it will lead to returned goods costing money and reputation.

Additionally, total value of investments used in the denominator of the ROI calculation is also subject to gaming behavior by the center managers. Since Accounting rules dictate that companies anticipate all losses but cannot record any gain in market value, the market value of the asset value in the denominator is not really a correct measure of the center's investment. In fact, managers have been known to sell company's fleet of cars and other assets in the last quarter to keep the denominator as small as possible.

Finally, use of ROI as the sole method for performance evaluation can lead to other dysfunctional decisions by the center managers. For example, Investment center managers have incentives to reject profitable projects whose ROI are below the current average ROI for the division because

---

[3] See "Blind Ambition" in Business Week, Oct. 23, 1995, pp. 78–92. According to Business Week article on Bausch and Lomb "Under pressure to beat sales target in 1993, contact lens managers shipped products that doctors never ordered while assuring them that they wouldn't have to pay until they sold the lenses".

accepting any such project would lower the overall ROI of the division. If the firm is in an industry where the initial projects earns a really high ROI, then managers will continue to search for such high-return projects; rejecting everything meanwhile.

Another disincentive created by ROI is the managers' reluctance to take high-risk projects. Since high-risk projects have a higher cost of capital and also a higher probability of failing, managers would not like any additional risk imposed on them. Also, a manager with a short-term horizon may pick projects that boost ROI in the short run even though they incur huge long-term costs.

67.2.4.2 Residual Income (RI)

To address some of the concerns related to ROI, some companies use residual income to evaluate performance. **Residual income** (RI) measures the "abnormal returns" earned by the division. Therefore a normal rate of return, measured either by the cost of capital or a required rate of return for the center. Is subtracted from division's profits. Under the residual income approach, manager has incentive to select the project as long as the residual income is positive, which simply means that the divisional profit rates are higher than the required rate of return.

However, RI has some problems of its own. Comparing RIs across divisions is difficult since larger divisions are more likely to have higher RI than smaller divisions, since RI is an absolute number.

Moreover, required rate of return is likely to be different for each division, depending on the riskiness and complexity of the project, making it to be a popular source of conflict in firms. Finally, RI suffers from the same problems as ROI, when it comes to the managers with short term horizon- they may try to increase short term RI by cutting on expenses like maintenance, jeopardizing future firm value and cash flows.

67.3   Transfer Pricing

Transfer price is a price paid by one division of a firm to another division for some goods and services they may exchange. The transfer price appears as revenue in the books of the supplying division and as cost in the books of the buying division. Since divisional managers care about their divisional income, choice of a transfer pricing policy can be an important tool in the hands of the upper management to control and influence the decisions of the managers.[4] As a general rule, the transfer price policy should be designed to accomplish the following objectives:

1. It should induce goal congruent decisions- that is, the system should be designed so that decisions that improve the division's profits will also improve company profits.
2. It should help measure the economic performance of the division.
3. It should provide each division with the information it needs to take better decisions.
4. It should be simple to understand and easy to implement.
5. Tax considerations and other objectives in International markets.

The variety of TP policies in common use[5] in American industry suggests that no single TP policy can be expected to be optimal for all firms. The structure of the firm and features of its environment are likely to determine if one policy is better for it than others.

The fundamental issue is that the transfer price should be similar to the price that would be charged if the product were sold to outsiders or purchased from outsiders, correcting for the savings in marketing and other transaction costs. The rule is complicated to use in situations when no outside market exists for the exact same goods (For example, an engine produced for a sports car of a specific brand) or the product is hard to specify in the beginning (For example, a large computer program).

67.3.1 Transfer Pricing Methods

There are three methods commonly used to determine transfer prices.[6] We will show how the choice of transfer pricing method can affect the companywide operating income as well as lead to suboptimal decision making by divisional managers-Suboptimal in the sense that they may maximize the division's income but may hurt the overall company profits.

Transfer prices can vary from very simple to very complex, depending on the nature of the product. Let's start with the simplest first:

67.3.1.1 Market Based Transfer Prices

Since market based transfer price will best simulate a competitive environment within the firm, a market based transfer price is best to use when there is a market price available reflecting the same quantity, quality and other features as the product being transferred. The argument is that if the firm cannot make a profit at the market price, then

---

[4] For a detailed literature review of transfer pricing as a coordinating mechanism, see Adams and Drtina (2008)

[5] In Tang's (1992) survey of Fortune 500 companies, there is evidence of companies using negotiated transfer pricing, market based transfer pricing as well as several variations of cost based transfer pricing.

[6] See for example, Kaplan (1982) for one of the firt detailed discussion of various TP methods.

the company is better off not producing it and purchasing it from outside. By using a market price in a competitive market, a company can not only take the correct make or buy decisions, it can also achieve almost all the objectives of a transfer pricing policy: goal congruence, measurement of manager's effort, division's autonomy, simplicity as well as performance evaluation. It is also likely to lead to minimum conflicts since most parties will consider market-based price to be fair.

A market price for a similar product is often used in the absence of an identical product. Conflict is likely to set in when the adjustment to the external price is made to reflect the true opportunity cost of the product to the firm. There are several reasons for this conflict. Firstly, internal transactions are usually cheaper than outsourcing due to synergies or interdependencies among products, reduced transportation costs, reduced marketing and administrative costs and reduced costs of bad debts. Making an adjustment to the market price to reflect all these savings is likely to be arbitrary. Secondly, even if the monetary costs are the same, firms are more likely to prefer to produce internally due to greater quality control, timely supply or greater control of proprietary information. When all these factors are included in the adjustment to the external price, the resulting transfer price may not seem fair to all.

Therefore, the ideal situation to implement a market based transfer price would be one where the managers are free to buy and sell in the outside market if it is in their best interest. If buyers cannot get a satisfactory price from the inside source, they are free to buy from outside. Similarly, if the seller can get a better price by selling it outside, it should be allowed to do so. In these circumstances, transfer price will represent exactly the opportunity cost to the seller of selling the product inside and lead to goal congruent decisions.

67.3.1.2 Cost Based Transfer Prices

If there is no external market for the intermediate good, then a transfer price based on some measure of cost may be considered:

67.3.1.3 Variable Cost Transfer Prices

Since the goal is to set a transfer price that reflects the true opportunity cost to the firm, variable production cost may be the most effective transfer price.[7] Variable costs also receive support from economists since they are considered to be closest to marginal costs, the method of choice for Economists.[8] The case for marginal cost is that that if

the transfer price is higher than the marginal cost, the supplying division would like to sell more than the optimal quantity and the buying division would like to buy less than the optimal quantity, leading to suboptimal production decisions.

However, transfer pricing at marginal cost has been criticized by some experts. Eccles (1985, 22) notes that transfer pricing without regard to fixed costs, overhead and profit for the selling division leads to an unfair measure of its contribution to the company. This criticism addresses the fact that the manufacturing division does not recover its fixed costs. Thus, the division would appear to be losing money.

A related problem with variable cost transfer pricing is that it creates incentives for the manufacturing division to distort variable cost upward, perhaps by misstating some fixed costs as variable costs. Since cost classifications for many costs are to some extent arbitrary, serious conflicts within the firm can arise.

Lastly, manufacturing division has the incentive to try to convert some of its fixed costs into variable costs, simply to get reimbursement, even though this conversion may be costly to the firm as a whole. For example, the division might choose to hire a costly consultant instead of hiring an employee or lease an asset instead of buying it to keep variable costs high and fixed costs low, since it gets reimbursed for the variable costs but not for the fixed costs.

There are several variations of variable costs to consider as transfer prices:

67.3.1.4 Standard Variable Cost Transfer Prices

A standard cost is a carefully determined cost of a unit of output. It may also represent the future cost of a product, process or subcomponent. Standard costs usually arise from the budgeting process of the company and represent the expected cost that will be used as a benchmark to compare with actual operating costs for performance evaluation purposes.

Standard costs are useful for both decision-making and control. Since, standard costs are known to all well before the actual variable costs become known, division managers have incentives to keep actual costs down, within the standards prescribed or their performance will suffer. Also using standard costs as benchmark allows top management to use deviations between actual costs and standard cost (Variance analysis) effectively for cost control and improvement in future performance. Lastly, since actual costs may vary from one batch to another, using standard costs are easier on the accounting system.

However, standard costs have been criticized for many reasons. First, depending on the philosophy of top management, standard costs may mean something that is currently

---

[7] For a theoretical model of Variable Cost based Transfer Pricing, see Vaysman (1996)

[8] Hirshleifer (1956) established conditions under which pricing internal transfers at marginal cost maximizes firm profit.

achievable or something that can be achieved with abnormal effort or luck. Too tight a standard might discourage the supplying division, while too loose a standard might not encourage maximum possible effort.

Second, most firms are reluctant to change standards during the year and often thereafter, unless a large, unexpected change occurs in a standard. Knowing the relative rigidity of the standards encourages suboptimal strategic behavior from the divisional manager. For example, manufacturing division managers, who are often involved in setting of standards, may overstate costs and keep a "slack" which they can consume, in form of lower effort, throughout the year. On the other hand, if standards are revised frequently during the year, divisional managers have less incentive to control costs. Therefore the decision to revise standards often involves the trade-off between loose standards and tight standards. Each of them can be a source of conflict between trading parties.

67.3.1.5 Actual Variable Cost Transfer Prices

A common method for arriving at the transfer price is to use the actual cost of production of the transferred product. A transfer pricing policy based on actual cost is usually easy to implement. It is also attractive from an internal accounting perspective since it generates an income statement that eliminates intra-company profits.

It is usually said that transfer prices based on actual costs provide no incentive to the supplying division to control costs, since the supplier is reimbursed for his costs. Also, since actual costs may vary from one batch to another, keeping track of batch costs and inventory may be hard for the accounting system. Another problem with actual cost based approach can arise in firms where operations are capacity constrained. When a firm is operating at capacity, production decision should optimize the use of the capacity rather than individual product's profit margin. In such cases, actual cost base transfer price will lead to a suboptimal quantity decision. In firms operating at full capacity, transfer price should instead be the sum of marginal costs and the opportunity cost of capacity, which would be the profit of the best alternative use of the capacity.

Because of the incentive and information problems described above, a commonly used variation of variable cost transfer pricing is to price all transfers at a **cost plus mark-up**. The mark-up may be in the form of a fixed fee to cover manufacturing division's fixed cost. Some firms choose a fixed fee to cover fixed cost plus a return on equity.

The most well known example of a markup is the *multiplicative* markup, in which the unit transfer price is determined by multiplying a cost measure by a fixed factor. For example, it might be set equal to 120% of the cost. Many

accounting textbooks[9] use the multiplicative method to illustrate the character of cost-plus transfer pricing.

An alternative to the multiplicative method is the *additive markup,* in which the unit transfer price is set at a fixed dollar amount over cost (e.g., the variable cost plus \$5.) Evidence for the use of such methods appears in a survey of Fortune 500 companies conducted by Price Waterhouse. The survey revealed that about 45% of all companies use an approach that "does not rely on percentage calculations" (Price Waterhouse, 1984, 13). Instead, "the cost and markup are maintained as two pieces of information and intra-firm profit is determined by adding up the markups".

Efforts to compare different transfer pricing methods show that additive markup is optimal among the class of cost-plus methods.[10] The argument is that additive markups are not only convenient to keep separate track of costs and profits, they also motivate the manufacturing division to reduce the cost so that it can maximize the number of units transferred (Hence the amount of mark-up earned). In contrast, under a multiplicative mark-up, the manufacturing division's income (Mark-up) is proportional to the production cost. Hence, the division is more interested in increasing the cost, and the resulting mark-up, than transferring the optimal quantity.

67.3.1.6 Full Cost Transfer Prices

Since most transfer pricing methods discussed so far suffer from some incentive problem or accounting complication, one alternative is to use a simple and objective transfer-pricing rule that will avoid wasteful disputes and arbitration costs. Since full cost is the sum of fixed and variable cost, it is easily available in the accounting system and cannot be changed by reclassifying a fixed cost as variable cost.

Another reason for the popularity of full cost transfer pricing is its ability to deal with the problem of changes in capacity. As a plant begins to reach capacity, opportunity cost to produce one more unit is likely to rise higher than variable costs. In such cases, full cost might be a closer approximation to opportunity cost than variable cost.

The incentive problem that most cost based systems suffer from is also present here-They provide no incentive to the manufacturing division to control costs, since the costs can always be recovered via transfer price. In fact, full cost method allows manufacturing division to transfer all of its inefficiencies to the buying division.

From optimality standpoint, the problem with full cost transfer pricing is that the quantity traded will always be suboptimal. Since full cost overstates the opportunity cost of producing and transferring one more unit internally,

---

[9] For example, Garrison and Noreen (2012)

[10] See Sahay (1997) and Sahay (2003).

manufacturing division would like to produce and transfer more units while the buying division would like to buy too few a units.

Despite all of these problems, full cost transfer pricing appears to be very common in practice. Perhaps the reason for its popularity is its simplicity and low cost of implementation. Scant theoretical research also suggests that with an appropriately chosen markup, the performance of actual cost based transfer pricing can be significantly improved, even though the markup leads to suboptimal resource allocation decision within the firm.[11] This result is consistent with the conventional wisdom of the accounting profession that judicious use of transfer pricing in a decentralized firm must trade off pricing efficiency with effective incentives for divisional decision making that would further the long term interests of the firm. Empirical evidence also suggests that firms that use cost based transfer pricing are well aware of its incentive problems, a vast majority of them choosing to price transfers above incremental production costs. (See Price Waterhouse, 1984 survey and Tang, 1992 survey)

67.3.1.7 Negotiated Transfer Prices

Several surveys of transfer pricing practices among large, decentralized firms document the use of negotiated transfer pricing policies. Such a policy lets divisional managers negotiate all aspects of an intra-firm transaction, including its price. Since divisional managers have superior local information, minimum interference from upper management in the trading decision enhances the 'flexibility gain' associated with decentralization. In particular, if the divisions have symmetric information, negotiated transfer pricing is likely to lead to efficient intra-firm trade: the divisions will choose to maximize the joint contribution margin, negotiations being limited to how this margin will be shared.

While negotiation is a fairly common method, it too has drawbacks. Firstly, divisional performance becomes sensitive to the relative negotiating skills of the two divisional managers. Moreover, if the supplying division manages to negotiate a price higher than the optimal price, implying that the receiving division will get lower than the optimal price, the quantity traded will be less than optimal, leading to lower firm-wide profits.

Secondly, negotiated transfer pricing can produce conflicts among divisions, leading to time and resource consuming arbitrations.

Finally, It is well known that negotiated transfer pricing suffers from under-investment due to the 'hold-up' problem. This problem has received much attention in the literature on incomplete contracts (see, for example, Williamson, 1985)

and occurs when the parties to a trade have the opportunity to make specific investments before the date on which they negotiate a price for the traded good. In such a setting, the investment costs must be considered 'sunk' when negotiating the price since they would have to be borne even if negotiations were to fail. Thus, the parties will be reluctant to incur any costs *ex ante*, and investments will be 'held up.'

Edlin and Reichelstein (1995) show that the hold-up problem associated with negotiated transfer pricing may be eliminated if the parties are allowed to sign a contract before the investments are chosen.[12] In essence, this prior contract (which serves as the *status quo*, should subsequent negotiations fail) provides protection for the costly investments. However, as argued by Holmstrom and Tirole (1991) inter-divisional transactions in a large firm are governed by incomplete contracts that are impossible to enforce, making the hold-up problem unavoidable.[13]

The discussion above suggests that no single TP policy can be expected to be optimal for all firms. The structure of the firm and features of its environment are likely to determine if one policy is better for it than others. It is somewhat surprising, therefore, that there has been little theoretical research on the comparison of alternative TP practices or on the setting up of general guidelines based on economic principles that can help a firm in its TP policy-making. Part of the reason for this state of affairs is that it is extremely difficult to address the TP problem without touching upon a host of other problems to some degree; a theory of TP is really part of a deeper theory of decentralization.[14] Another reason is the very variety of corporate TP practice which makes the problem important and interesting: it is difficult to analyze various methods of administered and negotiated TP[15] in a single theoretical model, in order to extract principles that can be generally applicable.

A few efforts in theoretical research have been made to produce a systematic study of the policies governing intra-firm transactions in a large, multi-divisional firm. The

---

[11] See Sahay (2003).

[12] Chung (1991) derives a similar efficiency result, also using a prior contract.

[13] See also the Executive Summary of the Price Waterhouse (1984) survey which reports: "Most companies (72%) state that they do not use formal contracts to document internal buy/sell agreements" (p. ii.).

[14] See Holmstrom and Tirole (1991) for an elaborate discussion of this point and for a model that endogenizes the need for transfer pricing in a more general study of possible decentralized forms. In this paper, however, we take transfer pricing as a control mechanism already in place in the firm.

[15] The literature classifies TP policies as *administered* (where most rules are laid down by headquarters) or *negotiated* (where participating divisions formulate their own rules.) Administered TP is either *cost*-based or *market*-based while negotiated TP often uses cost or market price as a starting point for negotiations. See the surveys of Eccles and White (1988) and Price Waterhouse (1984) for more details.

purpose of this research is to produce a systematic study of the policies governing intra-firm transactions in a large, multi-divisional firm. The results point towards emergence of a theory that addresses questions as to which TP policy is best for a given firm. Findings suggest that firms should be cautious in putting a particular TP policy in place, since the choice of the policy could significantly affect firm's profits, volume and efficiency of production and managers' incentives in taking other decisions important to the firm. In general, several economic factors have been identified that make one TP policy preferable to other. These economic factors include revenue and cost characteristics of the intermediate product transferred, the number of products, the price elasticity and the level of competitiveness of the external market faced by the firm.

In one of the first papers (BRS 99), a comparison of negotiated transfer pricing (NTP) and standard cost-based transfer pricing (SCTP) reveals general superiority of NTP. In a second paper (Sahay 2003) I show that the performance of actual cost-based transfer pricing with an additive markup is superior to any other cost-based policy in its class. Specifically, the actual cost-based method is shown to outperform several cost-based transfer pricing schemes, including SCTP. Sahay (2012, Working paper)[16] attempts to complete the ranking, showing the superiority of actual cost-based transfer pricing over negotiated transfer pricing, as long as the buying division's investment is sufficiently important.

67.4   Some Theoretical Models of Transfer Pricing

There is a considerable body of research available on theoretical transfer pricing models. However, only a few of these models are used in actual business situations. Although these models are not directly applicable to the real business situations, they are useful in conceptualizing transfer pricing systems. These models may broadly be divided into three types:
1. Models based on economic theory,
2. Models based on linear programming, and
3. Models based on Shapley value.

67.4.1 Economic Models

The classic economic model was first described by Hirschleifer[17] as a series of marginal revenue, marginal

cost and demand curves for the transfer of an intermediate good from one division to another. He used these curves to establish transfer prices that would optimize the total profit of the two business units.

The difficulty with this model is that it can be used only when a specifies set of conditions exists: It must be possible to estimate the demand curve of the product, there can be no alternative use of facilities used to make the intermediate good and the selling unit makes only one product which it transfers to a single buying unit. Such conditions are rarely met in the real world.

This model (and other economic models) assumes that transfer prices will be dictated by central management. It, therefore, denies the importance and benefits of negotiation among trading units. As a result, using the model may lead to delayed and dysfunctional decision making since negotiation between divisions leads to better decisions regarding price and quantity.

67.4.2 Linear Programming Models

The linear programming model is based on an opportunity cost approach. The model calculates an optimal production pattern for the firm and uses this production pattern to calculate a set of values that impute the profit contributions of each of the scarce resources. These are called *shadow prices* and one way of calculating them is called "obtaining the dual solution" to the linear program. If the variable costs of the intermediate good are added to their shadow prices, a set of transfer prices results that should motivate divisions to take optimal production decision for the firm. This is so because, if these transfer prices are used, each business unit will optimize its profits by producing in accordance with the patterns developed through the linear program.

If reliable shadow prices could be calculated, this model would be useful in arriving at the transfer prices. However, many simplifying assumptions are needed to make the model work. Some of these assumptions are that the demand curve is known, that it is static, that the cost function is linear and that the incremental profits from alternative use of factory can be estimated in advance. It is hard to meet these assumptions in the real world.

67.4.3 Shapely Value

Shapely value was developed in 1953 by L. S. Shapley as a method of dividing the profits of a coalition of individuals in proportion to each individual's contribution. It is used commonly in the theory of games as the most equitable solution to this problem.

---

[16] For a comparison of actual cost based with NTP, see Sahay, S. (2008)

[17] Jack Hirschleifer, "On the economics of Transfer Pricing," Journal of Business, July 1956, pp. 172–84.

Whether the same technique can be applied in transfer pricing is a debatable issue. Although the technique has been around for many years, few practical applications have been reported. A possible reason for its lack of popularity could be the complexity of computation unless there are only a few products involved in the transfer. Another reason is the general belief that the Shapley method is not valid for solving the transfer-pricing problem.

67.5   Optimal Transfer Price

Although no general rule always meets the goal of choosing the best transfer pricing policy, some guidelines[18] and boundaries can be established:

67.5.1 Minimum Transfer Price

The minimum transfer price acceptable to the selling division is clearly the variable unit cost of the product. Since, fixed costs are considered to be sunk costs, selling division would be interested in trading as long as its out of pocket costs are covered.

This is true, however, if the selling division has sufficient capacity to produce the entire order and would not have to give up some of its regular sales. In cases where capacity constraints force the division to either transfer an item internally or sell it externally- that is, it cannot produce enough to do both, then the selling division would expect to be compensated for the contribution margin on those lost sales. In general, if the transfer has no effect on fixed costs, then from the selling division's standpoint, the transfer price must cover both the variable cost of producing the transferred units and any opportunity costs from lost sales.

From the firm's standpoint, transfer is desirable if (1) the total cost of producing the good (by both divisions) is less than the price it can receive for the good in the outside market and (2) it does not pay more to produce the good internally than it would have to pay to buy it in the marketplace. The only transfer price that would achieve both these objectives for the firm is the formula suggested below:

$$\text{Minimum Transfer Price} = \text{Seller's variable cost} \\ + \text{opportunity cost.}$$

67.5.2 Maximum Transfer Price

From the buying division's perspective, the trade is beneficial only if its profit increases. For that, it must be able to sell the final product for more than the transfer price plus other costs incurred to finish and sell the product. So the maximum transfer price that it can offer is the difference between the final price and additional variable costs incurred by the buying division. This transfers the entire surplus from the transaction to the selling division. For example, if a good can be sold in the market for \$30 and the variable costs of selling and buying division are \$10 and \$6 respectively, then the buying division can pay up to \$24 (\$30 − \$6). Anything more would put him at a loss.

In cases where the buying division has an outside supplier available, the choice of maximum transfer price is simple. Buy from an inside supplier only if the price is less than the price offered by the outside supplier. This may lead to suboptimal decision from the firm's standpoint. For example, if a good can be sold in the market for \$30 and the variable costs of selling and buying division are \$10 and \$6 respectively, then per unit profit for the company is \$14. However, if the transfer price is set at \$12 and an outside supplier is willing to provide it for \$11, the buying division would buy it from outside, even though the company could have spent only \$10 in producing it internally. So, the highest transfer price in this case is \$11, the alternative maximum price from an outside source.

67.5.3 Idle Capacity and Transfer Price

As mentioned before, idle capacity can significantly change the economics and psychology of transfer pricing. If selling division has large unused capacity, more than enough to satisfy the buying division's demand, then it would be interested in the proposal as long as its variable cost is covered. Since there would be no lost sales, there is no opportunity cost, minimum transfer price would be equal to variable cost. (\$10 in the example above).

Maximum transfer price would, once again, depend on the availability of an outside price. If the buying division can buy similar product from an outside vendor for \$15, then it would be unwilling to pay more than \$15 as the transfer price.

Thus combining the requirements of both the selling and the buying division, the acceptable range of transfer price would be between \$10 and \$15.

67.5.4 No Idle Capacity and Transfer Price

Generally, firms prefer internal transactions to external ones. After all, firms are organized as a collection of profit centers

---

[18] See general guidelines regarding Transfer Prices in Horngren et al. (2011)

due to synergies and savings in transaction, bargaining, marketing and other administrative costs and would prefer to produce a part internally than buy it from outside. Other reasons for firms to prefer an internal transaction may be quality control, timely delivery and security of proprietary information. So if the selling division is selling its entire capacity production to outside market, it would have to divert some product away from its regular customers to be able to fill an order from the buying division.

In such cases, the minimum transfer price would be unit variable cost plus the unit contribution margin from lost sales. To continue the example above, suppose that the selling division is selling its entire capacity of 1,000 units to outside market at $15 per unit and receives an order of 200 units to be supplied to the internal division. So the minimum price, that the selling division is willing to consider as transfer price, is its unit variable cost ($10) plus the unit contribution margin on lost sales ($5 = $15 − $10).

The maximum transfer price, as before, would be equal to the cost of buying it from an outside supplier. Thus, if the outside vendor is ready to supply the good at $18 as in the example above, the transfer price would be set between a range of $15 and $18.

67.5.5 Some Idle Capacity and Transfer Price

If the selling division has only some idle capacity, but not enough to fill the entire order by the buying division, then it would have to divert only some of the product from its regular customers, keeping the opportunity cost portion of the minimum transfer price at a lower level. In our example, suppose the selling division is currently selling only 900 units when its capacity is 1,000 units, it can supply only 100 units internally without diverting sales from its regular customers. However, the buying division needs 200 units. Let us also assume that the selling division will have to supply the entire order of 200 units, having to divert 100 units from its regular customers. Thus the minimum transfer price would be variable cost ($10 × 200 units = $2,000) plus the unit contribution margin on lost sales ($5 × 100 units = $500). Since the transfer quantity is 200 units, unit transfer price would be $12.50 = ($2,000 + $500)/200 units.

67.6 International Transfer Pricing

In today's global markets, companies may produce goods and services domestically and sell them internationally or produce them outside the country and sell them here. Since the profit is earned in the country of the sale, differences in tax laws can be the leading determinant of transfer pricing choices. Tax factors include, not only income taxes but also payroll taxes, custom duties, tariffs, sales taxes, environment related taxes and other government levies on organizations. Lax tax laws in one country can encourage a Multi-National Corporation to deploy resources in that country. Choice of an appropriate transfer pricing policy can help in minimizing a company's tax burden, foreign exchange risks and can lead to better competitive position and governmental relations. Although domestic objectives such as divisional autonomy and managerial motivation are always important, they often become secondary when international transfers are involved. Companies would typically focus on charging a transfer price that would reduce its tax bill or that will strengthen a foreign subsidiary.

For example, a company may choose a low transfer price for parts shipped to a foreign subsidiary to reduce custom duty payments or to help the subsidiary to compete in foreign markets by keeping the subsidiary's costs low. On the other hand, it may choose to charge a higher transfer price to draw profits out of a country that has high income tax rates to a country that has lower tax rates or out of a country that has stringent control on foreign remittances.

Transfer pricing is a major concern for multinational companies as highlighted by the fact that approximately 80% of Fortune 1,000 firms select transfer pricing policies keeping financial, legal and other operational considerations in mind. In addition, intra-firm trade accounts for about 55% of the trade between Japan and EU, and 80% of the trade between US and Japan.

Tax authorities are aware of the incentives to set transfer prices to minimize taxes and import duties. Therefore, U.S. Internal Revenue Service (IRS) pays close attention to taxes paid by multinational companies within their boundaries. At the heart of the issue are the transfer prices that companies use to transfer products from one country to another. For example, in 2004, the IRS fined U.K. based pharmaceutical manufacturer GlaxoSmithKline $5.5 billion in back taxes and interest, stemming from a transfer pricing dispute regarding profits from 1989 to 1996.

It is not surprising, therefore, that most countries have restrictions on allowable transfer prices. Section 482 of the U.S. Internal Revenue Code governs taxation of multinational transfer pricing. This section requires that transfer prices between a company and its foreign subsidiary, for both tangible and intangible property, equal the price that would be charged by an unrelated third party in a comparable transaction. In other words, transfer prices must reflect *an arm's length price*. For tangible goods, the best method is considered to be *a comparable controlled price* between unrelated firms. While this method is theoretically sound, it is difficult to use in practice because intra firm transactions are hard to compare with open market transactions.

The next best method is the *resale price approach*, which is allowed if there is no comparable price available.

The method allows all costs and a reasonable profit to be deducted from the resale value.

The third method is the *cost plus approach*, where an appropriate mark up is added to the manufacturing cost to determine the transfer price.

In summary, companies are allowed to use a market based or a cost plus method as long as the surplus represents margin on comparable transactions. In addition, international tax treaties regulate allowable transfer pricing methods.

Eun and Resnick (2012) discuss a case study where the firm's choice of a transfer pricing policy with low markup on cost versus a transfer pricing policy with a high markup result in different incomes and tax burdens for the companies operating in countries with different tax rates, exchange restrictions, import duties and other regulations affecting transfer prices.

67.7 Limitations of Financial Control Systems

An important goal of a business enterprise is to optimize shareholder returns. However, optimizing short-term profitability does not necessarily ensure optimum shareholder returns in the long run. At the same time, the need for ongoing feedback and performance evaluation requires companies to measure a division's performance in the short term, usually at least once a year. Overemphasis on financial controls may be dysfunctional for this as well as many other reasons:

Firstly, it may encourage short-term actions that are not in the company's long-term interests. For example, the manager may use inferior raw materials to keep costs down, adversely affecting company's goodwill and future sales.

Secondly, divisional managers may not undertake useful long-term actions, in order to maximize short-term profits. For example, managers may not invest sufficiently in research and development' since R&D investments must be expensed in the year in which they are incurred but their benefits show up only in the future.

Thirdly, using short-term profit maximization as the sole criteria for performance evaluation can lead to gaming behavior by managers. For example, divisions may set profit targets that can be achieved very easily so that they are never penalized for missing the target. This would result in suboptimal quantity produced and sold. Leading to lower profit for the firm.[19]

Lastly, tight financial control may motivate managers to manipulate data to meet current profit targets. For example, managers may make inadequate provision for bad debts and warranty claims. Managers may also be tempted to falsify data-that is, deliberately provide inaccurate information.[20]

In short, relying on financial control measures alone is insufficient to ensure long-term profit maximization. The solution is to use a blend of financial (costs, revenue, profits) and nonfinancial measures (quality, customer satisfaction, innovation) that would achieve the long-term success of the organization.

Conclusion

This study analyzes the performance of various transfer pricing policies used by American industries and compares them with regard to firm profits and efficient decision making by divisional managers.

Since most firms use transfer prices to assess internal transactions, choice of a transfer pricing policy affects the reported income of the divisions. Since managers are typically evaluated and compensated based on the reported income of their divisions, the method used for setting transfer prices directly influences the decisions delegated to them. This makes transfer pricing policy an important tool in the hands of upper management for motivating managers to take decisions that are in the best interest of firm's overall profits.

The variety of TP policies in common use suggests that no single TP policy can be expected to be optimal for all firms. This study compares the performance of popular TP policies in a large multi-divisional firm. We seek to identify economic factors that make one TP policy preferable to other. These economic factors may be revenue and cost characteristics of the good transferred, the number of products, the price elasticity and the level of competitiveness of the external market faced by the firm.

The findings of the study suggest that firms should be cautious in putting a particular TP policy in place since the choice can be crucial to firms' performance. It seems that among the class of cost based TP policies, an additive markup over variable cost is most desirable from the optimal resource allocation standpoint because it motivates the seller to reduce costs and increase production.

---

[19] Another example of tactics used by manager is found in Bausch and Lomb where unusually long credit terms were extended to customers in exchange for big orders. See "Blind Ambition" in Business Week, Oct. 23, 1995, pp. 78–92.

[20] According to Business Week article on Bausch and Lomb "Under pressure to beat sales target in 1993, contact lens managers shipped products that doctors never ordered while assuring them that they wouldn't have to pay until they sold the lenses".

Alternative Models for Evaluating Convertible Bond: Review and Integration

68

Lie-Jane Kao, Cheng-Few Lee, and Po-Cheng Wu

Abstract

The price of a convertible bond is determined by three state variables, they are: the firm's market value or price of common stock, the value of the firm's straight bond, and the credit risk of the issuing firm. Depending on the assumptions made for the three state variables, various pricing methods for the evaluation of convertible bonds are developed. This paper classifies pricing methods into three types: (1) The graphical approach by Brigham (Journal of Finance 21:35–54, 1966); (2) The calculus approach by Baumol et al. (The Quarterly Journal of Economics 80: 48–59, 1966), Poensgen (Industrial Management Review 7: 76–92, 1965, Industrial Management Review 7: 83–88, 1966), Frankle and Hawkins (Journal of Finance 30: 207–210, 1975); and (3) The option pricing approach pioneered by Brennan and Schwartz (The Journal of Finance 32: 1699–1716, 1977, Journal of Financial and Quantitative Analysis 15(4): 907–929, 1980) and Ingersoll (Journal of Financial Economics 4: 289–321, 1977a, Journal of Finance 2: 463–478, b), which can be further classified by as those based on the structural default model or the reduced-form default model. The three types of pricing methods are reviewed and compared in this article.

68.1 Introduction

A convertible bond which entitled to a set of fixed claims is a bond that can be converted into common stocks at the owner's option subject to conditions specified in the indenture. Therefore, convertible bonds are two instruments in one: one is the straight debt instrument, which guarantees a fixed payment for the life of the bond. The second instrument is the equity portion, which allows the bondholder to reap the gains due to increase in the equity value by conversion. By issuing convertible bonds, the firms can lower its cost of debt funding compared to straight debt alone. For investors, convertible bonds offer greater stability of income than common stock.

There are two varieties of convertible bonds: callable vs. non-callable convertibles. Usually, callable convertibles have the same provisions as their non-callable counterparts, except they are subject to redemption by the issuing company at the prevailing call price prior to maturity. In most cases, the call provision is standard in indentures and is especially important in case of convertibles. As one can think of a non-callable convertible as a special case of callable convertible with sufficiently large call price, in this study, convertibles with call provision are always assumed.

In general, the price of a convertible is determined by three state variables and four decision variables, respectively.

e-mail: lee@rbs.rutgers.edu

The three state variables are: (1) The price behavior of the firm's market value or common stock; (2) The value of the corresponding straight bond; (3) The credit risk of the issuing firm. The four decision variables are: (1) The call policy of a company with convertibles outstanding as when to announce a call, the call price for redemption payment, the specification of the call notice, ... etc.; (2) The conversion policy includes the date of conversion, the conversion price as how much one share of common stock costs at conversion, or equivalently, the conversion ratio as how many shares of common stocks one debenture is convertible; (3) The put provision that allows the investor to sell the convertible bond to the issuer for specific prices on specific dates prior to maturity; (4) The capital structure of the firms, e.g., whether there are any other senior claims of the firms.

In literature, various assumptions are employed regarding the aforementioned three state variables. The assumptions spans from deterministic to stochastic. By assuming a constant interest rate r and deterministic stock price growing at a constant rate g, the graphical method of Brigham (1966) is a representative of the deterministic approach. To describe the dynamics of these state variables more rigorously, stochastic models are developed, which can be further divided into calculus and option pricing approach, respectively. In the calculus approach, one considers the issuing firm's market value (or stock price) on a specific date in the future as a random variable. While in the option pricing approach, the dynamics of the issuing firm's market value (or stock price) for a time period in the future is modeled as a random process. The representatives of the calculus approach include Baumol et al. (1966), Poensgen (1965, 1966), and Frankle and Hawkins (1975). The option pricing approach dominates the pricing of convertible bonds, which is pioneered by Brennan and Schwartz (1977, 1980) and Ingersoll (1977a, b).

Both the deterministic and calculus approach ignore the possibility of bankruptcy by the issuing firm, therefore the convertible bonds might be mispriced. The option pricing approach, on the other hand, considers the likelihood of default based on either type of default models: the structural model (Merton, 1974; Black and Cox, 1976) or the reduced-form model (Jarrow and Turnbull, 1995). In the one-factor structural model, the issuing firm's market value follows a geometric Brownian motion. Later Brennan and Schwartz (1980) proposed a two-factor structural model with a stochastic interest rate. Nyborg (1996) extends Brennan and Schwartz's two-factor structural model by including a put provision and floating coupons feature.

In contrast to the structural model, the more recent literature use reduced-form model in which stochastic stock price instead of the firm's market value is modeled. These include the works by Goldman Sachs (1994), Ho and Pfeffer (1996), Tsiveriotis and Fernandes (1998), Davis and Lischka (1999), Takahashi et al. (2001), Ayache et al. (2003), Lau and Kwok (2004).

This work reviews the literature on convertible debt valuation including the deterministic, static stochastic, and dynamic stochastic models. The outline of the paper is as follows. In Section 68.2, the graphical model with deterministic assumptions is stated. Section 68.3 states the calculus models with static stochastic stock price and/or straight bond's price. Section 68.4 gives the option pricing approach by modeling the dynamics of a firm's market value as a stochastic process. In Section 68.5, a numerical approach, e.g., the tree approach, for the valuation of -convertible bonds in reduced-form models is given. Section 68.6 concludes.

68.2 Deterministic Model: Graphical Approach

Brigham (1966) proposed a descriptive graphical model for the valuation of a callable convertible where the stock price is assumed to grow at a constant rate g and therefore the time-t conversion value satisfies

$$C_t = P_0(1+g)^t R \qquad (68.1)$$

where R is the conversion ratio, P_0 is the initial stock price. By assuming a constant market interest rate i, the time-t straight–debt value is

$$B_t = \sum_{k=1}^{T-t} \frac{I}{(1+i)^k} + \frac{M}{(1+i)^{T-1}}$$

where M is the par value of the bond, T is the maturity date, and I is the coupon paid each period.

This model is presented in Figure 68.1. Logically, the value of the convertible bond cannot be less than its straight-debt as well as conversion value. Therefore, the higher of the conversion value curve CC_t and straight-debt value curve BM forms a floor curve (BXC_t) for the market value of the convertible represented by the curve (MM'). At relatively low conversion value, the convertible's floor curve is represented by the straight debt value, BX. Above the segment BX, the shaded area refers to the value attached to the conversion feature of the security. Thus, at the lower levels of equity prices, the convertible's market value is a composite of its straight debt value and a premium for the conversion feature. Moving to higher levels of equity prices, there exists a premium between the conversion value XC_t and the convertible's market value MM' due to the risk exposure reduction by holding the convertibles. As the conversion value increases to exceed the call price VM, the convertible's market value approaches M' where the convertible's market value intersects with the conversion value. The reasons for

Dollars
Fig. 68.1 Hypothetical model of a convertible bond (Reprinted by permission from Brigham, E. F. "An analysis of convertible debentures: theory and some empirical evidence," *Journal of Finance* 21, p. 37)

the intersection are threefolds: (1) The likelihood of a call increases as the conversion value increases; (2) Loss protection against interest rate risk diminishes; (3) The dividend yield of the common stock exceeds the fixed coupon yield of the convertible as the conversion value increases. In summary, a convertible's market price is a complex interaction between its straight debt value and a premium associated with the expected future market price of the underlying equity security. This complex interaction, however, is not explicitly specified in Brigham's work. In the following, the interaction is accounted for by random characterization of the stock price and/or the straight debt value.

68.3 Calculus Approach: Static Stochastic Models

Baumol et al. (1966) present a convertible-security valuation model that separates the interaction between debt and equity attributes in the valuation of convertible securities by considering the time-t value $C = max(C_s, C_b)$ of a convertible as

$$
C_s = ps
$$
$$
+ \int_0^{\bar{B}/ps} f(i, t_0)[\bar{B} - i(t)ps]di(t), \tag{68.2}
$$
$$
C_b = \bar{B}
$$
$$
+ \int_{\bar{B}/ps}^{\infty} f(i, t_0)[i(t)ps - \bar{B}]di(t), \tag{68.3}
$$

where $\bar{B}$ = equivalent straight debt value; s = number of equity securities issued upon conversion; p = price of the

equity security at present t_0; $i(t)$ = date-t to date-t_0 equity security's price relative; $f(i, t_0)$ = subjective probability assessment of $i(t)$ at t_0, when $t > t_0$. Equation 68.2 specifies that C_s is composed of two values: the conversion value ps and the insurance value of the debt character as the stochastic price relative $i(t)$ varies between 0 and $\bar{B}/ps$ at the end of time horizon t. Equation 68.3 states that C_b is a combination of two values: the straight debt value $\bar{B}$ and the value assigned to the conversion feature as the stochastic price relative $i(t)$ varies between $\bar{B}/ps$ and ∞ at the end of time horizon t.

Later, Baumol et al. (1966) extended their previous model by introducing the ex ante notion that the convertible security holder is interested in the future conversion value of the convertible security as follows:

$$
C = \int_0^{\infty} i(t)psf(i, t_0)di(t)
$$
$$
+ \int_0^{\bar{B}/ps} f(i, t_0)[\bar{B} - i(t)ps]di(t), \tag{68.4}
$$

In this model, the first term represents the conversion value in all possible states of the price relative $i(t)$ from 0 to ∞, while the second term represents the insurance value of the debt character as the stochastic price relative $i(t)$ varies between 0 and $\bar{B}/ps$.

Both in Brigham (1966) and Baumol et al. (1966), the market interest rate is flat and bond's straight debt value was treated as an exogenously determined constant. By including the nature of interest-rate changes, an explicit characterization of the random nature of a convertible security's bond value would lead to a robust model of the market setting of convertible securities. In Poensgen (1965), both the stochastic stock price and stochastic straight debt value are explicitly considered. Be more specific, on an arbitrarily date when conversion is possible, Poensgen (1965) suggests the expected price of the convertible security as

$$
E(P) = \int_0^{\infty} \left[y\int_0^y h\left(\frac{x}{y}\right)dx + \int_y^{\infty} xh\left(\frac{x}{y}\right)dx \right] g(y)dy, \tag{68.5}
$$

where x = the stock price (or conversion value); y = the straight debt value; $h(x/y)$ = the conditional probability of x for a particular bond value y; $g(y)$ = the probability of occurrence of the bond value y (unconditional). Note that the probability of joint occurrence of the stock price x and bond value y is $h(x, y) = h(x/y)g(y)$. It can be shown Equation 68.5 is logically equivalent to the following:

$$E(P) = \underbrace{\int_0^\infty \left[\int_0^\infty xh(x, y)dx \right.}_{\substack{\text{Expected stock} \\ \text{value}}} + \underbrace{\left. \int_0^y (y - x)h(x, y)dx \right]}_{\substack{\text{Value of floor} \\ \text{guarantee}}} dy,$$

(68.6)

$$E(P) = \underbrace{\int_0^\infty yg(y)dy}_{\substack{\text{Expected} \\ \text{straightdebt} \\ \text{value}}} + \underbrace{\int_0^\infty \int_y^\infty (x - y)h(x, y)dx\,dy}_{\substack{\text{Expected value of} \\ \text{the conversion} \\ \text{option}}},$$

(68.7)

Equation 68.6 specifies that the value of the convertible security is the expected stock price plus the value attached to the floor guarantee for a stochastic straight debt value, y. This formulation is identical to Equation 68.4 by Baumol et al. (1966) model except for the assumption by Poensgen (1965) that y is a random variable. Alternatively, in Equation 68.7, the first term evaluates the value of a straight debt, while the second term evaluates the value of a warrant with exercise price y by integrating over all possible straight-debt value, y.

By showing that there was no statistically significant correlation between bond yield variability and stock prices, Poensgen (1965) claims that Equation 68.7 is analytically equal to

$$E(P) = \int_0^\infty yg(y)\,dy + \int_y^\infty (x - y)f(x)dx,$$

(68.8)

where $f(x)$ is the probability density function of x. Based on Equation 68.8, Poensgen (1965) suggests that the distribution of stock prices, x, is truncated on the left by the straight-debt value. This assertion facilitates Poensgen's (1965) subsequent empirical work dealing with the truncated distribution of convertible security returns. Nevertheless, the integration in Equation 68.8 does not equal to that in Equation 68.7. Therefore, the subsequent work of Poensgen (1965) on the truncated distribution of convertible security returns is not of great help.

Later, Frankle and Hawkins (1975) adopted Poensgen's valuation model for convertible securities to explore the link between the beta of a convertible security and the beta of the underlying common stock by assuming independence of the stock and straight bond prices so as to obtain

$$E(CB) = \int_0^y yh(x)\,dx + \int_y^\infty xh(x)\,dx,$$

(68.9)

where $E(CB)$ = expected price of the convertible security; y = straight-debt value, x = log of the stock price relative;

$h(x)$ = log-normal distribution of stock price relatives. By assuming a constant straight debt value and following the previous direction of Poensgen (1965) by asserting that the probability density function of the log of the stock price relatives are truncated at a constant value a, Frankle and Hawkins (1975) presents the expected log return on the convertible bond as:

$$E_{en(i(t))CB} = a \int_{-\infty}^a \frac{1}{\sqrt{2\pi}\sigma_x} e^{-(1/2)[(x-\mu_x)/\sigma_x]^2} dx$$
$$+ \int_a^\infty x \frac{1}{\sqrt{2\pi}\sigma_x} e^{-(1/2)[(x-\mu_x)/\sigma_x]^2} dx. \quad (68.10)$$

Frankle and Hawkins (1975) proceed to derive an explicit form for the beta of a convertible security based on the beta of the underlying common stock. This relationship is presented as follows:

$$Beta = \rho \frac{\sigma_x}{\sigma_m} \left[1 - \phi\left(\frac{a}{\sigma_x} \right) \right],$$

(68.11)

where ρ = correlation coefficient between x and the market m; σ_x = standard deviation of common stock return; σ_m = standard deviation of market return; ϕ = the cumulative normal function. It is noted by Frankle and Hawkins that Equation 68.11 implies that the beta of a convertible security is less than or equal to that of its underlying common stock. Thus, Frankle and Hawkins (1975) derive an upper bound for the convertible security's beta. Nevertheless, the result by Frankle and Hawkins (1975) in Equation 68.11 is false as Equation 68.9 is falsely derived. Further efforts need to be done for a valid relationship between the beta of a convertible security and that of its underlying common stock.

The next major advance in convertible-security valuation evolved from the option pricing theory originated by Black-Scholes (1973) and the risky zero-coupon bond's pricing by Merton (1974). In the option pricing approach, the firm's market value over time is modeled as a stochastic process, and three possibilities of the termination of a convertible bond are considered: conversions by the bondholders, maturity of the bond, called back or default of the firm. The following Section considers option pricing approach for the valuation of convertible bonds.

68.4 Option Pricing Approach: Dynamic Stochastic Model

When pricing a convertible bond, one needs to consider the conversion and put strategies of bondholders, the call back policy and the default mechanism of the firm. For simplicity, we'll not consider the put option in this study. Therefore, in the following, we focus on the three decision variables of a

convertible bond: the conversion strategy, call back policy, and default mechanism.

Ingersoll (1977a) is the first to derive the optimal conversion strategy for bondholders and optimal call policy for the firm in a perfect, frictionless market with no dividends and constant conversion terms. According to Ingersoll (1977a), for a firm with a capital structure consisting of equities and convertible bonds only, the optimal conversion strategy satisfies the following lemma:

Lemma 68.1 *If the perfect market, no dividends, and constant conversion terms assumptions are valid, then a callable convertible will never be converted except at maturity or a call.*

With the additional assumptions of no call notice and flat interest rate, Ingersoll (1977a) gave the optimal call strategy for a company as

Lemma 68.2 *If the conditions for the above lemma hold, the optimal call strategy is to call when the firm's market value reaches the call price divided by the dilution factor γ, the fraction of the equity that the bond holders posses if they convert.*

One advantage of Ingersoll's result (1977a) is that it captures the dilution effect as convertible bonds are converted into common stocks (Schönbucher, 2003). With this advantage, Ingersoll (1977a) decomposed the price of a non-callable convertible bond G into a straight discount bond F (with the same principal as the convertible bond) and a warrant W as

$$G(V, \tau; B, 0, \gamma) = F(V, \tau; B, 0) + W(\gamma V, \tau; B) \quad (68.12)$$

where B is the balloon payment, τ is the time to maturity, c is coupon payment, γ is the dilution factor, $W(\gamma V, \tau; B)$ is the warrant price with underlying price γV and exercise price B. The initial condition for W satisfies

$$W(\gamma V, 0; B) = \max(\gamma V_T - B, 0)$$

where V_T is the firm value at maturity. By assuming the firm's market value V follows a geometric Brownian motion and default occurs if V falls below an exogenously determined barrier (Merton, 1974; Black and Cox, 1976; Longstaff and Schwartz, 1995; Briys and Varenne, 1997), or an endogenously determined barrier due to the strategic decision of the firm (Leland, 1994; Leland and Toft, 1996), Ingersoll (1977a) derived analytically the values of the straight discount bond F and the warrant W using the option pricing theory for a risky debt.

In the case of a callable convertible bond, the bond's price H is decomposed into a straight discount bond F, a warrant W and an additional term representing the cost of the call which reduces the value of the callable convertible bond relative to its non-callable counterpart as

$$\begin{aligned}
H(V&, \tau; K(\tau), 0, \gamma) \\
&= F(V, \tau; B, 0) + W(\gamma V, \tau; B) \\
&+ Z^{2(r-\rho)/\sigma^2} [F(\gamma V', \tau; B', 0) - F(\gamma V', \tau; B'/\gamma, 0)]
\end{aligned}$$
$$(68.13)$$

where $K(\tau)$ is the call price of the convertible and $Z = K(\tau)/\gamma V$, $B' = Be^{(r-\rho)\tau}$; $V' = V e^{(r-\rho)\tau}$. In another paper by Brennan and Schwartz (1977), the partial differential equation for the price of a convertible with call provisions and dividends is derived based on the following conversion and call strategies.

Lemma 68.3 *It will never be optimal to convert a convertible bond except immediately prior either to a dividend date or to an adverse change in the conversion terms, or maturity.*

Lemma 68.4 *The firm's optimal call strategy is to call the bond as soon as its value, if it is not called, is equal to the call price.*

Later, in addition to the simplistic capital structure assumed by Ingersoll (1977a) and Brennan and Schwartz (1977) consisting solely of equity and convertible bonds, Brennan and Schwartz (1980) include senior straight debts in a firm's capital structure and develop a two-factor structure model with stochastic firm's market value and interest rate for the valuation of a convertible bond. Brennan and Schwartz (1980) found that often the additional factor representing stochastic interest rates had little impact on the prices of convertible bonds. Later, Nyborg (1996) extends the two-factor model of Brennan and Schwartz (1980) with a put provision and floating coupons feature.

Nevertheless, due to the complexity of the convertible's contractual provisions so the number of parameters used is large and the firm's market value is unobservable, the aforementioned approach can be impractical and there might be no analytical solutions for the valuation of a convertible bond. Instead, practitioners often use the equity price as the underlying for the valuation of a convertible bond and some numerical approaches are employed. In the following Section, the prevalent numerical approach, i.e., the tree method, is given.

68.5 Numerical Approach: Tree Method

The most widely used numerical approach for the pricing of a convertible is the tree approach. The approach has the capability to handle various convertible bond provisions. The main procedure of the tree approach for convertible bond pricing is stated as follows:

First, consider the firm's stochastic price S as the underlying, which follows a lognormal Ito process of the form:

$$dS = \mu(S, t)Sdt + \sigma SdW \qquad (68.14)$$

where $\mu(S, t)$ is the drift term, σ is the volatility, and W is a standard Brownian motion. A binomial tree is built in a risk neutral world for the development of the stochastic price S in Equation 68.14 according to the Cox et al. (1979). Each node on the tree represents a possible future stock price. Then a backward induction procedure starting from the maturity is applied, a maximum convertible bond value on each node is decided according to the stock price and the action taken according to the provisions, e.g. convert, put, call, hold or redeem the bond. Finally the current value of convertible bond can be calculated. The credit risk of the convertible bond is considered by setting a risky discount rate with the credit spread of the issuer (Goldman Sachs, 1994) or adding a default node (Hull, 2009) with the default probability which is decided by the default intensity of the issuer.

More complex model with multi-factors, such as adding a stochastic interest rate, or with time-varying default intensity, volatility, and interest rate is also applicable with tree model (Ho and Pfeffer, 1996; Hung and Wang, 2002; Ammann et al., 2003; Carayannopoulos and Kalimipalli, 2003; Chambers and Lu, 2007). Ho and Pfeffer (1996) employed a two-dimensional binomial tree for the stochastic stock price and interest rate in their two-factor model, in which all the cash flows are discounted at the risky rate (i.e., risk free plus credit spread). Correlated default intensity and stock price is discussed in Andersen and Buffum (2003). However, Brennan and Schwartz (1980) and Goldman Sachs (1994) indicated that the major factor which decides the convertible bond value is the equity price. Adding additional factor, such as dynamic interest rate, into consideration had little impact on the value of convertible bond.

Conclusion

This article reviews the various models developed for the valuation of callable convertible bonds, which is a dual option problem: on the one hand, the shareholders determine the optimal call and bankruptcy policies so as to maximize the equity value, on the other hand, the

bondholders determine the optimal conversion strategy so as to maximize the convertible bond's value. As the bondholders' optimal conversion strategy depends on the firm's call strategy, and the firm's optimal call strategy in turn depends on the bondholders' voluntary conversion strategy, the dual option problem is complex with no simplifying solution on it.

Studies further taking into account of the bankruptcy costs, tax benefits, and capital structure of the bond issuer as well as the refunding costs and a call notice period can be found in Liao and Huang (2006). In Lee et al. (2009), the association between investor protection and the security design of convertibles, as measured by the expected probability of converting the convertibles at maturity is examined. For convertible bonds with non-standard features, such as the refix clause that alters the conversion ratio (shares per bond) or conversion price, subject to the share price level on certain days between issue and expiry, the convertible bond's coupons can be allowed to change with time, or at conversion the bondholders receive a combination of shares and cash instead of just shares, more advanced models need to be developed to take into account of the versatile designs of the convertible bonds.

A Rationale for Hiring Irrationally Overconfident Managers

Oded Palmon and Itzhak Venezia

Abstract

The viability of managerial overconfidence is perplexing since it has been shown to lead managers to erroneous and costly decisions. This paper addresses this issue by exploring the impact of managerial overconfidence on managerial effort, executive compensation, and the welfare of stockholders and managers. Overconfidence affects managerial effort directly and indirectly. The direct effect is that the optimal effort chosen by managers is positively related to their level of overconfidence. The indirect impact is through the influence on stockholders' choices of contract parameters. Thus, managerial overconfidence helps mitigate the well-known conflict of interest between managers and stockholders that induces managers to exert effort levels that are lower than the socially optimal levels. We construct a measure of the combined welfare of managers and stockholders and show that it is positively related to managerial overconfidence, thus providing an explanation to the persistence of this bias.

Behavioral biases • Incentive options • Managerial effort • Overconfidence

69.1 Introduction

Confidence is a highly regarded personality trait in our society. Confident people are often greatly admired and lack of confidence is considered as an unattractive quality. Overconfidence is a well documented psychological bias whose consequences can vary.[1] Whereas overconfident individuals can bring about bold and imaginative innovations, their overconfidence may also lead them to make erroneous and costly decisions.

There are two main schools of thought regarding the definition and measurement of overconfidence. First, Alpert and Raiffa, 1982, and their followers, concentrate on the calibration (or precision) of probabilities. They consider someone to be overconfident if her view of the precision of

[1] See, e.g., DeBondt and Thaler, 1995; Shefrin, 2000; Barberis and Thaler, 2003; Baker et al., 2006, and Camerer and Malmendier, 2007.

her estimate of some variable is too high, or put differently if she attaches too low a probability to the event that she may be wrong. This type of bias is akin to underestimating the standard deviation of some variables.[2] According to the other school of thought, people are considered overconfident if they are too optimistic regarding their accomplishments and attach too high a probability of success to their endeavors; that is, they overestimate the expected values of the results of their effort. The difference between the two schools of thought can be summed up in that the first one assumes that overconfident people overestimate their ability to predict the future whereas the second assumes that they overestimate their ability to change the future.

There is evidence that people overestimate their ability to do well on tasks (Frank, 1935), are unrealistically optimistic about future events, expect good things to happen to them more often than to their peers (Weinstein, 1980; Weinstein and Klein, 2002; Kunda, 1987), and are even unrealistically optimistic about pure chance events (Marks, 1951; Irwin, 1953; Langer and Roth, 1975). Most individuals see themselves as better than the average person and most individuals see themselves better than others see them (Taylor and Brown, 1988). They also rate their abilities and their prospects higher than those of their peers.[3] For example, new business owners think that their business is more likely to succeed than other businesses like theirs' (Cooper et al., 1988).

In the context of financial decisions, Odean, 1998; Barber and Odean, 1999, Grinblatt and Keloharju, 2009, show that overconfidence leads to "excessive" trading. Statman et al., 2004, show that overconfidence can create a disposition effect, and Ben-David et al., 2008, argue that overconfidence intensifies this effect. Daniel et al., 1998, demonstrate that investor overconfidence (in the "too high precision" sense) may cause excessive volatility. Ben-David ,et al. 2007, conduct a large survey documenting that managers mis-calibrate their estimates of key financial variables leading them to distorted decisions. Malmendier and Tate, 2005a, b, and Malmendier et al., 2007, argue that overconfidence leads managers to prefer using internal financing to external financing, causing the often observed "pecking order of financing." Roll, 1986; Hayward and Hambrick, 1997, and

Malmendier and Tate, 2008, show that overconfidence of managers may lead to value-destroying mergers. Landier and Thessmar, 2009, show that optimism causes managers to prefer short term to long term financing.

Some researchers also analyze the constructive effects of overconfidence. Cassar and Friedman, 2007, show that the initiation of start up activities is positively related to overconfidence. Gervais and Goldstein, 2007, argue that overconfidence enhances team productivity. Within a standard principal agent framework, Chen and Chen, 2007, show that an agent's effort increases with overconfidence. Oyer and Schaefer, 2005, discuss the role of optimism in sorting employees. Bergman and Jenter, 2007, analyze the effect of optimism (and other sentiments) on compensation.

This paper adds to the literature as it analyzes the effect of the overconfidence of effort averse managers on the effort they exert, their compensation and consequently on the welfare of the firm's stakeholders. Our analysis shows that managerial overconfidence causes stockholders to alter the compensation contract they offer to managers and induces managers to exert higher effort levels. It thus helps mitigate the well known conflict of interest between managers and stockholders that induces managers to exert effort levels that are lower than the optimal levels that would be contracted if effort was observable and contractible.[4] Moreover, the benefits to stockholders from the managers' higher effort levels are larger than the monetary equivalents of the manager's utility losses due to their suboptimal (under the realistic distribution) contract and effort level choices. These findings provide an explanation for the persistence of managerial overconfidence.[5]

The paper is constructed as follows. In Section 69.2 we present the model. In Section 69.3 we describe the analysis method, and in Section 69.4 we present the results. In Section 69.5 we conclude.

---

[2] Lichtenstein et al., 1982, provide a review of the findings on overconfidence in many professions. For overconfidence among Physicians and nurses see: Christensen-Szalanski and Bushyhead, 1981, and Baumann et al., 1991; among investment bankers: Staël von Holstein, 1972; among engineers: Kidd, 1970; among entrepreneurs: Cooper et al., 1988; among lawyers: Wagenaar and Keren, 1986; among negotiators: Neale and Bazerman, 1990; among accountants: Bar-Yosef and Venezia, 2008; and among managers: Russo et al., 1992.

[3] For example, when a sample of U.S. students assessed their own driving safety, 82% judged themselves to be in the top 30% of the group (Svenson, 1981).

[4] This is consistent with the empirical findings of Puri and Robinson, 2007.

[5] The persistence of overconfidence has been explained by evolutionary biology. Persistence of overconfidence among managers has been explained by, Gervais and Odean, 2001, by the attribution effect. Bernardo and Welch, 2001, explain this by an evolutionary process where the overconfident group compensates for its mistakes by its innovative capabilities and hence is able to survive. Goel and Thakor, 2008, and KrÄahmer, 2003, suggest that overconfidence enhances the chances of managers to succeed in tournaments or contests. Overconfident managers are more willing to take risks and are therefore more likely ending up winning tournament-like contests. Heaton, 2002, points out that in the corporate environment, optimistic managers are not likely to be arbitraged away.

69.2 A Model of Compensation Contracts and the Resulting Managerial Effort

We consider a one period Holmstrom, 1979,-type model where a risk neutral firm employs an overconfident, risk averse and effort averse manager.[6] We assume that the cash flows, X, of the firm depend on the manager's effort and on exogenous stochastic factors. The manager is assumed to provide some effort which is the minimum necessary to run the firm and hence may be considered observable, but can provide also unobservable extra-effort. The more extra-effort the manager exerts, the higher will be the expected cash flows. Because stockholders cannot observe managers' extra-effort, managerial compensation may depend on the firm's cash flows (which depend on extra-effort), but cannot depend directly on extra-effort.

We assume that the cash flows of the firm, X, are Lognormally distributed with the following distribution function:

$$f(X) = \exp\{ -0.5\{ [\log(X) - \mu(Y)]/\sigma\}^2\}/(X\sigma\sqrt{2\pi}) \tag{69.1}$$

where Y denotes the managerial extra-effort (a managerial choice variable), and $\mu(Y)$ and σ denote, respectively, the mean and the standard deviation of the underlying normal distribution of the natural logarithm of X. We assume that managerial effort increases cash flows, and that overconfident managers overestimate the impact of their effort on cash flows. Formally, we use the following specification for the subjective impact of effort on output:

$$\mu(Y) = Ln(\mu_0 + 500\,\lambda Y) - \sigma^2/2 \tag{69.2}$$

where λ denotes the degree of overconfidence. We assume that stockholders have realistic expectations, which are represented by $\lambda = 1$, and that managers use $\lambda > 1$ to form their expectations. Thus, f(X) can be written as f(X, λ), where f(X, $\lambda = 1$) represents the realistic cash flow distribution while f(X, $\lambda > 1$) represents the cash flow distribution as viewed by overconfident managers. For notation brevity, we suppress the λ in f(X, λ). By the known properties of the Lognormal distribution, the mean and variance of X equal $e^{[\mu(Y)+0.5\sigma^2]}$ and $\left[e^{[2\mu(Y)+\sigma^2]}(e^{\sigma^2} - 1)\right]$, respectively. Thus, it follows from Equation 69.2 that a person with a λ overconfidence measure believes that the mean of the cash flows X is:

$e^{\mu(Y)+0.5\sigma^2} = \mu_0 + 500\lambda Y$, and that their coefficient of variation is approximately σ.[7] Since managers and stockholders differ in their perception of the distributions of cash flows, one must be careful in their use. In what follows we refer to the distribution of cash flows as seen by stockholders as the realistic distribution and will make a special note whenever the manager's overconfident beliefs are used.

Except for her overconfidence, the manager is assumed to be rational and to choose her extra-effort so as to maximize the expected value of the following Constant Relative Risk Aversion (CRRA) utility function:

$$U(I, Y) = -I^\alpha(Y_0 - Y)^\beta \tag{69.3}$$

where I denotes the manager's monetary income, The parameter α is negative, and the utility function represents a constant relative risk aversion of $1-\alpha$. Y_0 is a parameter that represents the upper bound of the extra-effort level that the manager can invest in the firm. Since β is negative, the higher is Y_0 the lower is the derivative of U(I,Y) with respect to Y. Y_0 can therefore be considered as representing managerial "efficiency" parameter in the sense that the higher it is, the lower is the disutility of extra-effort that results in a given increase in expected cash flows. Y_0-Y may be thought of as managerial leisure.

Since stockholders cannot observe the manager's extra-efforts they propose compensation schemes that depend on the observed cash flows, but not on Y. Stockholders, which we assume to be risk neutral, strive to make the compensation performance-sensitive in order to better align the manager's incentives with their own. Stockholders offer the manager a compensation package that includes three components: a fixed wage (W) that she will receive regardless of her extra-efforts and of the resulting cash flows, options with a strike price (K) for a fraction (s) of the equity of the firm, and stock grants for another fraction (g) of the firm.

The following timeline of decisions is assumed. At the beginning of the period the firm chooses the parameters of the compensation contract (K, g, W, and s) and offers this contract to the manager. Observing the contract parameters, and taking into account the effects of her endeavors on firm cash flows and hence on her compensation, the manager determines the extra-effort level Y that maximizes her expected utility. At the end of the period, X is revealed, and the firm distributes the cash flows to the manager and to the stockholders and then dissolves. The priority of payments is as follows. The firm first pays the wages (or only part of them if the cash flows do not suffice). Next, the

---

[6] In our model we assume symmetry of information between the manager and the firm regarding the distribution of cash flows of the firm except for the different view of the effect of the manager's effort on cash flows.

[7] More precisely the square of the coefficient of variation is $\left[e^{\sigma^2} - 1\right]$ which can be approximated by σ^2 since for any small z, e^z-1 is close to z.

manager is paid the value of the options, $sMax[(X - K - W),0]$. Out of the remaining equity, the manager receives the fraction, g, and the shareholders, the fraction 1-g.

The manager therefore receives the cash flows I(X) defined by:

$$I(x) = \begin{cases} X \\ (1-g)W + gX \\ (1-g)[W + sMax(X - W - K, 0)] + gX \end{cases}$$

$$when \begin{cases} X \leq W \\ W \leq X \leq W + K \\ W + K \leq X \end{cases}$$

(69.4)

In the above cash flows formula the first range covers the case where cash flows do not suffice to pay the entire wage. The second range covers the case where the options expire out-of-the-money, and the manager gets the promised wage and a fraction g of the remaining cash flows. The third range represents cash flows large enough so that the options expire in-the-money. In addition to the wage, the manager receives a proportion, s, of the value of the firm above the threshold value of K, and a proportion, g, of the rest. The expected utility of the manager $E\{U[I(X),Y]\}$ which governs her behavior, and her expected compensation $E[I(X)]$, can be obtained by integrating her utility, $U[I(X),Y]$, given in Equation 69.3 and her compensation, I(X), given in Equation 69.4, respectively. We note that the manager chooses the effort level so as to maximize the expected utility using her perception of the distribution of the firm's final cash flows, while stockholders choose the parameters of the compensation contract using the realistic cash flows distribution to calculate the expected cash flows and managerial compensation.

Shareholders receive all cash flows that are not received by the manager. Since stockholders are risk neutral and rational, stockholders' equity value (SEV) is the expected value of these payments, using the realistic distribution function, and hence[8]:

$$SEV = E(Cashflows) - E[I(X)]$$
$$= \int_0^\infty Xf(X)dX - E[I(X)]$$

(69.5)

While the derivation of the optimal contract for any set of exogenous parameters is conceptually straightforward,

unfortunately, closed form solutions cannot be obtained in our integrative model. Hence, we resort to simulations to evaluate the optimal contracts and analyze their properties. In addition, the Black-Scholes model cannot be used to evaluate the executive stock options since it takes the values of the underlying asset as given, whereas a crucial aspect of the managerial incentive scheme of our model is that managerial extra-effort and firm value are endogenously determined. We therefore introduce a model that simultaneously simulates the manager's optimal extra-effort level as well as the expected values of the executive stock options, the stock grants the manager receives, and shareholders' equity for each compensation package. We check the robustness of our results by using alternative parameters for the manager's utility function, the impact of managerial extra-effort on firm performance and the distribution functions of the cash flows.

Our model shares many similar features with the Holmstrom, 1979, model. The latter however assumes that stockholders have a huge computational capacity and can designate a compensation structure that maximizes the manager's expected utility and their stocks' values, assumption that is quite strong.[9] To partially circumvent this problem, we employ the following slightly different procedure. We first look at all the possible contracts that may be offered. That is, we consider all possible combinations of K, g, s, and W and then find for each combination the manager's optimal extra-effort, $Y^*_{K,g,s,W}$. We then find for each contract the resulting stockholders equity, the expected managerial compensation and other contract characteristics. We identify the contracts that yield high equity values, and refer to the contracts that are in the top stockholders' equity decile as optimal contracts. Then we consider the impact of managerial overconfidence on stockholders' values that are associated with the optimal and, for robustness, also the other contracts.

69.3 The Simulation Procedures

In calibrating the parameters for the simulations we try to approximately conform to other studies that simulate decisions with effort aversion such as Bitler et al., 2005, and studies that explore the effect of overconfidence on corporate decisions, such as Malmendier and Tate, 2005a, b, 2008.[10] Accordingly, we set the parameters in our base case as follows. The coefficient of variation, σ, equals 0.3, and thus the standard deviation is 0.3E(X). Since the expected cash flows serve as numeraire, the volatility is determined solely by the coefficient

---

[8] Discounting the cash flows by an appropriate risk-adjusted discount rate would yield a linear transformation of equity values. To simplify the presentation, and as is common in the literature, we abstract from that.

[9] For an extensive criticism of this approach see, e.g., Rubinstein, 1998; March, 1994; Simon, 1957, and Sade et al., 2006.

[10] See Appendix A for the explanation for the calibration of our model.

of variation. The expected cash flows as viewed by an over-confident manager with an overconfidence measure of λ are E(X) = 45,000 + 500λY (i.e., μ_0 = 45,000). The efficiency parameter is Y_0 = 30, and the risk aversion and effort aversion parameters are α = −1, and β = −0.50, respectively.

We consider overconfidence levels between λ = 1.5 and λ = 2.5. When λ = 1.5, the manager believes that the contributions of her extra-effort to expected cash flows are 50% higher than the realistic estimates.[11] If the manager exerts an effort of Y = 20 (this is a round figure close to the average actual effort determined in the base case simulations), she overestimates her contribution to expected cash flows by about 9.1% of total expected cash flows. When λ = 2.5, the corresponding figure is about 27.3%.

The robustness of the results to deviations from the base case combination of parameters is examined by simulating with several alternative sets of exogenous parameters. We repeat the analysis for many alternative sets of the exogenous parameters: the manager's risk and extra-effort aversion, α and β, her efficiency, Y_0, and the volatility measure of cash flows, σ.[12]

We approximate the outcomes of the set of all possible contracts by considering several combinations of several representative values of each of the parameters. We set the upper limits of each of the parameters at such levels that would be high enough so as not to be restrictive. We use integer values between 0% and 5%, in steps of 1%, for the percentage, s, of the firm that is given out as options.[13] For the percentage of the firm paid out as equity, g, we choose values between 0% and 0.5% in steps of 0.1% and for W we choose values between 2 and 12 in steps of 2. For the representative strike prices we choose values (in 1,000 s) between 15 and 55, in steps of 5. We choose the upper limit of 55 since it is higher than the expected value of the firm without the manager making any extra-effort (45) and close enough to the expected firm value obtainable when the manager exerts the maximal possible effort (60). We do not consider strike prices higher than 55 since out-of-the money options do not turn out optimal in our initial simulations. When the strike price equals zero, an option becomes identical to a stock and hence many of the alternative contract replicate each other (and are less attractive to stockholders when compared with contracts that include

options with higher strike prices). In order to make a clear distinction between options and stocks, and because granting options with a very low strike price is very rare, we do not consider contracts with options whose strike prices are close to 0. In selecting the number of alternative values for each variable within the limits we weigh the tradeoff between precision and computational feasibility.

The above choice of representative values for each parameter yields 1944 different contracts for each set of exogenous variables and overconfidence level (6 option percentages X 6 equity percentages X 6 wage levels X 9 strike prices =1944).

For each contract we then find the manager's optimal extra-effort by solving, for $Y \leq Y_0$, the following problem (using Mathematica):

$$Max_Y \int_0^\infty U(I(X),Y)f(X,\lambda)dX \qquad (69.6)$$

where I(x) is given by Equation 69.4, U[I(X),Y] by Equation 69.3, and f(X,λ) by Equation 69.1.

Under each overconfidence level, we sort the contracts according to the resulting stockholder equity and identify those that yield the top 10% of stockholder equity (which for brevity we call "optimal") as well as those in each stockholder equity quintile. We then analyze how overconfidence affects the resulting welfare of the stockholders and the managers assuming that an "optimal" contract is chosen.

69.4 Results and Discussion

In Table 69.1 we present simulations results that facilitate the examination of the impacts of overconfidence on the effort choice of managers, the expected managerial compensation and the welfare of managers and stockholders. In the five panels of this table we present the resulting managerial effort, the expected value of stockholders equity value (SEV), the expected values of the managerial compensation evaluated using the realistic distribution of cash flows, and the corresponding values when the managers' optimistic distribution of cash flows is employed. We sort all contracts according to the SEV's and present averages for six subsets of contracts: the optimal contracts and five contract quintiles by stockholder equity.

In panel A we present the contract outcomes for the optimal contracts and in panels B-E the outcomes for all the contracts. These panels are presented by increasing levels of overconfidence levels from the lowest, λ =1, representing a rational manager in panel B, to the most overconfident one with λ = 2.5 in panel E. The rows in

---

[11] For other overconfidence levels, the belief of the manager is that the contributions of her extra-effort to expected cash flows are (λ−1)100% higher than the realistic estimates.

[12] Because of scaling there is no need to conduct robustness checks for the expected cash flows.

[13] Initial simulations indicate that the optimal option awards are likely to be in the range 0–5%, hence we use this range in the present simulations. Similar considerations lead us to the determination of the range for the other variables in our simulations.

Table 69.1 Effort levels, Y, stock holders equity values (SEV), and managerial expected compensation according to the objective distribution of cash flows as well as their own subjective distribution. The results for the optimal contracts only are presented in Panel A, and those for all contracts, in panels B–E. Base case: $\alpha = -1$ $\beta = -0.5$, $Y_0 = 30$, $\sigma = 0.3$

	Effort (Y)	Stockholders equity value, SEV	Expected compensation, realistic valuation	Expected compensation, managers subjective valuation
	1	2	3	4
Panel A: Results for the optimal contracts only for all overconfidence levels				
Overconfidence level, λ

Bottom quintile	7	48,094	405.4	493.1

panels B-E correspond to optimal contracts and contract quintiles by decreasing SEV.

We first note that the average SEV's of the optimal contracts increase as managerial overconfidence increases (see column 2 of Panel A; for example, when λ =1 the SEV is 53,347 and when λ = 2.5 it is 56,589, an increase of about 6%).

Overconfidence increases the willingness of the mangers to exert effort because it increases their estimate of the value of the options and stock grants they receive. One observes from column 1 of Table 69.1 that the average effort levels increase with overconfidence. This is true both for the optimal contracts presented in Panel A and for the other contracts (see column 1 in panels B-E of Table 69.1). The

tendency of the more overconfident managers to work harder for any given set of contract parameters is also gleaned from the following analysis. We examine for all contracts the differences in the effort levels that are chosen by managers with two consecutive (i.e., 1.5 vs. 1, 2 vs. 1.5 and 2.5 vs. 2) levels of overconfidence, holding fixed all the contract parameters. We find that in 98% of the contracts managers with a higher overconfidence level exert more extra-effort.[14]

---

[14] Our examination excludes contract pairs where effort levels equal zero for the two consecutive overconfidence levels (about 7.5% of the pairs).

Table 69.2 Stakeholders welfare measure SWM (Sum of stockholders equity value, SEV, and managers' no-effort certainty equivalent measure, NECE) evaluated according to both managers' and stockholders' distribution functions for different levels of overconfidence. Base case: $\alpha = -1$, $\beta = -0.5$, $Y_0 = 30$, $\sigma = 0.3$

Overconfidence measure, λ	NECE manager's evaluation	NECE realistic evaluation	Stockholders equity value, SEV	Stakeholders welfare measure, SWM, managers evaluation	Stakeholders welfare measure, SWM, realistic evaluation
	1	2	3	4	5
1	123.3	123.3	53,347	53,471	53,471
1.5	100.8	64.0	55,069	55,170	55,133
2	94.8	37.4	55,993	56,088	56,030
2.5	94.4	23.9	56,589	56,683	56,613

The higher penchant of the overconfident manager to exert extra-effort suggests that, compared with employing realistic managers, stockholders can obtain from overconfident managers a given effort level and equity value for a lower-cost (according to stockholders' expectations) compensation contract. Indeed, one observes from column 3 of Panel A in Table 69.1 that as overconfidence rises, expected managerial compensation declines. The managers' average expected compensation according to the realistic distribution function falls from 748.5, when they are not overconfident to 494.3 when $\lambda = 2.5$, a difference of about 34% (see column 3).[15] However the average expected compensation according to the managers' optimistic distribution of cash flows rises from 748.5 to 1032.1, an increase of about 38% (see column 4). Most of the increase in the SEV accompanying the rise in overconfidence is due to increased effort. For example, out of the increase of 3,242 (= 56,589–53,347) in average SEV that stockholders enjoy when the overconfidence level grows from 1 to 2.5, only about 8% (254.2/3,242) is due to the savings in expected pay. Most of the rise in the SEV is due to the increase in the effort that the overconfident manager exerts (it rises from Y = 18.2, when λ =1, to 24.2, when $\lambda = 2.5$, see column 1 of Panel A).

Since it has been shown that as overconfidence rises, so do stockholders' equity values and the manager's expected compensation according to her optimistic beliefs, it may seem that overconfidence increases the welfare of the stakeholders of the firm (in this case just stockholders and managers). However, the results show that overconfidence causes the manager to receive lower expected compensation according to the realistic distribution, and it also induces her

to work harder than a realistic manager. One may therefore wonder whether overconfidence improves the total welfare of the stakeholders when that welfare is measured according to the realistic distribution function. Stockholders are assumed to be risk neutral, and hence their welfare can be measured by their SEV. Managers on the other hand are risk averse and effort averse, and therefore their expected utility must be converted to some "certainty equivalent" in order to be able to aggregate these measures. Thus, we define a "no-extra-effort and certainty equivalent" (NECE) measure as the amount of certain compensation requiring no extra-effort that the manager would accept in lieu of any given contract with the ascribed effort and compensation. Having converted the welfare of the manager into monetary units, the stakeholders' welfare is captured by the sum of the NECE and the SEV, which we call the Stakeholders Welfare Measure (SWM).[16]

In Table 69.2 we present the effects of overconfidence on the welfare of the stakeholders: the stockholders and the managers. Since the managers are overconfident we calculate their welfare using both the objective (realistic) distribution function and their subjective distribution. This is done so as to assess their welfare both from their own point of view as well as from society's perspective. Since stockholders are assumed realistic, their wealth is calculated only using the realistic distribution function.

One observes from columns 1 and 2 of this table that the welfare of the managers decline with overconfidence. This comes as no surprise since it demonstrates that they suffer from their unrealistic view of their talents which leads them to exert too much effort. On the other hand we observe from column 3 that the welfare of the stockholders increases with managerial overconfidence. Moreover, the total welfare measure, SWM, presented in columns 4 and 5 are positively related to overconfidence. This shows that the stockholders' gains from the managers' over-exertion of effort and poor

---

[15] These expected compensation levels equal, respectively, 1.4% and 0.87% of the corresponding equity values. These ratios are similar to the average of the actual ratios of CEO compensation to company profits (recall that in our one period model stockholders equity corresponds to profit) in a sample of 350 large companies in 2008, based on data from http://www.forbes.com/lists/2009/12/best-boss-09_CEO-Compensation_CompTotDisp.html, and http://money.cnn.com/magazines/fortune/fortune500/2008/full_list.

[16] The payments are virtual and outside the model so that incentives and thus efforts would not be affected. This is the widely used Pareto optimality condition for welfare improvement.

Table 69.3 Sensitivity analysis of effort levels, Y, stock holders equity values (SEV), expected compensation, according to rational stockholders valuation and to managers valuation, and stakeholders' welfare measure, (SWM), to variations in risk aversion α (Panel B), effort aversion β (Panel C), coefficient of variation, σ, (Panel D), and efficiency measure, Y_0, (Panel E). The base case is presented in Panel A

Effort (Y) 1	Stockholders equity value, SEV 2	Expected compensation, rational stockholders valuation 3	Expected compensation, managers valuation 4	Stakeholders welfare measure, rational valuation (SWM) 5

2 32.6	60,685	594.1	1089.0	60,715
2.5 33.4	61,143	558.3	1330.7	61,171

choice of contracts exceed the managers' losses. This impact helps explain the persistence of the overconfidence bias as it demonstrates that overconfidence could be welfare enhancing and thus could be a socially desirable character feature.

Table 69.3 depicts the results of sensitivity analyses that examine the effects of a change in each of the parameters on the behavior of stockholders and managers and on welfare. The analyses provide a robustness check by showing that the results obtained from the base case are qualitatively immune to changes in the parameters. We present the results of only one or two changes in each of the exogenous parameters (α, β, Y_o, and σ), but we conduct many other simulations, and all provide the same qualitative results.[17]

The results in Table 69.3, demonstrate that SEV, effort, and SWM increase with overconfidence under all the

---

[17] These simulations may be obtained from the authors upon request.

parameter combinations that we use. This shows that our results are robust to a wide range of alternative parameter values.

Conclusion

Our study addresses an important puzzle in Corporate Finance: Why does the market allow managerial overconfidence to persist in spite of being associated with value-destroying managerial decisions. The current study argues that managerial overconfidence helps mitigate an agency problem whereby realistic managers exert less than the socially optimal level of effort since their effort is not observable and can be compensated only through its impact on a stochastic firm value. Stockholders in this case offer managers a compensation contract that includes bonus stocks and/or options in order to better motivate them. By simulating the compensation contracts that stockholders offer, and the

corresponding effort choices of overconfident managers, we demonstrate that overconfident managers exert more effort than realistic ones, thus partially mitigating the above mentioned agency problem. We also construct a measure of the total welfare of the firm's stakeholders (managers and stockholders), taking into account the effort and risk choices of managers. We show that this total welfare measure increases with managerial overconfidence. This indicates that some aspects of managerial overconfidence may be socially beneficial and may offset their other value destroying effects. These favorable impacts on firm value and total welfare increase the viability of overconfidence in the long run.

69.5   Appendix A: Calibration of the Parameters of the Base Case Calculation

We refer to Hek, 1999 and Bitler et al., 2005 for the choice of the parameters and the shape of utility functions that depend also on leisure.[18] Hek finds the power utility useful in explaining technological change. Bitler et al., 2005 find that behavior of entrepreneurs can be explained by this type of utility function. We start with our base case $U(I,Y) = -I^{\alpha}(Y_0 - Y)^{\beta}$, where $\alpha = -1$ and $\beta = -0.50$. We choose $\alpha = -1$ (a measure of constant relative measure of risk aversion of 2) since this is the parameter that has been widely used in studies of overconfidence: Malmendier and Tate, 2005a, b. We examine however also other parameters as robustness checks.[19]

We assume that the function $\mu(Y)$ is given by $\mu(Y) = Ln(\mu_0 + Y/2) - \sigma^2/2$. By the known properties of the Lognormal distribution, the mean and variance of this distribution equal $e^{[\mu(Y) + 0.5\sigma^2]}$ and $\left[e^{[2\mu(Y) + \sigma^2]}(e^{\sigma^2} - 1)\right]$, respectively. The parameters μ_0 and σ were selected so that, in the absence of managerial extra-effort, the expected cash flows per share are 45,000 and the coefficient of variation (i.e., the ratio of the standard deviation to the expected value) of the cash flow per share is 0.3. Since the expected cash flows serve as numeraire, the ratio of the standard deviation of the cash flows per share to their expected value is a surrogate for the standard deviation of stock returns.

---

[18] We found additional estimates of effort disutility (leisure utility) in the following papers: Prasch, 2001; Kiker and Mendes-de-Oliveira, 1990, and Dowell, 1985. These estimates varied in the functional form as well as in the level of effort aversion.

The Statistical Distribution Method, the Decision-Tree Method and Simulation Method for Capital Budgeting Decisions

Cheng-Few Lee and Tzu Tai

Abstract

The information needed for capital budgeting is generally not known with certainty. Therefore, capital-budgeting procedures under conditions of uncertainty should be developed to improve the precision of assessment of the value of risky investment projects. The three alternative methods are introduced to analyze the capital budgeting decisions under uncertainty. Statistical distribution methods, decision tree methods, and simulation methods are three interrelated methods of analysis for capital-budgeting decisions under uncertainty because all of them allow the statistical distributions of the net present values to be explicitly estimated. Under these methods, an interval rather than a point estimate of the expected NPV will be presented. Hence, the stochastic methods discussed in this paper are generally more objective and general than the traditional capital budgeting methods under the assumption of certainty in cash flows.

70.1 Introduction

Investment decision rules, or capital budgeting decisions, involve the evaluation of the possible capital investments of a firm according to procedures that will ensure the proper comparison of the cost of the project. That is, the initial and continuing outlays for the project, with the benefits, the expected cash flows accruing from the investment over time. Under the assumption of certainty in both cash flows and the cost of funds, several methods can be used by a manager to evaluate an investment decision. The simple methods, such as the accounting rate-of-return or payback method, are useful in that they are easily and quickly calculated. However, they both disregards the time value of money by the failure to discount cash flows back to the present. To compare the two cash flows, future cash amounts must be discounted to the present by the firm's cost of capital. Only in this way will the cost of funds to the firm be equated with the benefits from the investment project. Thus, other methods, such as the net present value, profitability index, and the internal rate-of-return methods, are superior in that explicit consideration is given by them to both the cost of capital and the time value of money.

Decision situations can generally be classified into three types: certainty, risk, and uncertainty. The distinction between risk and uncertainty is that risk involves situations in which the probabilities of a particular event occurring are known, whereas with uncertainty these probabilities themselves are not known. The riskiness of an investment proposal is generally defined as the variability of its possible returns. Throughout this paper the terms "risk" and "uncertainty" will be used

interchangeably, although the strict difference between them is not a matter to be taken lightly.

In reality, the information needed for capital budgeting is generally not known with certainty. Economic factors peculiar to investment, competition, technological development, consumer preferences, and labor market conditions are a few of the factors that make it virtually impossible to foretell the future. Consequently, the revenues, costs, and economic life of investment projects are less than certain. Therefore, capital-budgeting procedures under conditions of uncertainty should be developed to improve the precision of assessment of the value of risky investment projects. The sources of uncertainty may be either the net cash inflows, the life of the project, or the discount rate. The main sources of uncertainty related to the net cash flows may result from the unknown and random production of the project. The uncertainty associated with the life of the project may be due to deterioration or obsolescence. The uncertainty of discount rates may be attributable to changes in market rates-of-return or risk-free rates-of-return. Three alternative methods are introduced to analyze the capital budgeting decisions under uncertainty mainly related to the net cash flows. Statistical distribution methods, decision tree methods, and simulation methods are three interrelated methods of analysis for capital-budgeting decisions under uncertainty because all of them allow the statistical distributions of the net present values to be explicitly estimated. Under these methods, an interval rather than a point estimate of the expected NPV will be presented. Hence, the stochastic methods discussed in this paper are generally more objective and general than the traditional capital budgeting methods under the assumption of certainty in cash flows.

This paper is organized as follows. In Section 70.2, we present the statistical distribution model which mainly focused on the expected value and variance of NPV. Then, we introduce the specific formula from Hillier (1963) that combines the assumption of mutual independence and perfect correlation between different sources of the cash flows. The conditional-probability distribution approach from Bonini (1975) is also illustrated to deal with the moderate correlation between the cash flows. Section 70.3 we present the decision-tree method which can be used to analyze some investment opportunities involving a sequence of investment decisions over time. Section 70.4 describes simulation method which does not restrict the number of random variables in capital budgeting uncertainty. The example of simulation model developed by Hertz (1964) can be found in this section. Concluding remarks appear in Section 69.5.

70.2 The Statistical Distribution Method

With the introduction of risk, a firm is no longer indifferent between two investment proposals having equal net present values. Both expected value of net present value and its

standard deviation (σ_{NPV}) should be estimated in performing capital-budgeting analyses under uncertainty. A NPV approach under uncertainty can be defined as

$$\tilde{N}PV = \sum_{t=1}^{N} \frac{\widetilde{C_t}}{(1+k)^t} + \frac{S_n}{(1+k)^N} - I_0 \qquad (70.1)$$

where $\widetilde{C_t}$ is the uncertain net cash flow in period t, k is the risk-adjusted discount rate, S_n is the salvage value, and I_0 is the initial outlay. The mean of the NPV distribution and its standard deviation can be defined as:

$$\overline{NPV} = \sum_{t=1}^{N} \frac{\overline{C_t}}{(1+k)^t} + \frac{S_n}{(1+k)^N} - I_0, \qquad (70.2a)$$

$$\sigma_{NPV} \left[\sum_{t=1}^{N} \frac{\sigma_t^2}{(1+k)^{2t}} + \sum_{\tau=1}^{N} \sum_{t=1}^{N} w_t\, w_\tau\, Cov(\tilde{C}_\tau, \tilde{C}_t) \right]^{1/2} (\tau \neq t),$$
$$(70.2b)$$

where σ_t is the variance of the cash flow in the tth period, w_t and w_τ are the discount factors, $1/(1+k)^t$ and $1/(1+k)^\tau$, in the tth and τth periods, respectively. $Cov(\widetilde{C}\tau, \widetilde{C_t})$ is used to measure the covariability between the cash flow in the tth and τth periods. It is well known that:

$$\text{Cov}(\widetilde{C}\tau, \widetilde{C}_t) = \rho_{\tau t} \sigma_\tau \sigma_t, \qquad (70.3)$$

where $\rho_{\tau t}$ is the correlation coefficient between the cash flow in the ith period and that in the τth period. In one special case, the cash flows are perfectly correlated over time. If such is the case, then the deviation of the actual cash flow from the mean of its corresponding profitability distribution of expected cash flows for the period gives us the information that cash flows in future periods will deviate in a similar fashion. In other words, Equation 70.2b can be rewritten as[1]:

---

[1] Substituting Equation 70.2b and letting $\rho_{\tau t} = 1$, we have

$$\sigma^2{}_{NPV} = \left[\sum_{t=1}^{N} \frac{\sigma_{Xt}^2}{(1+k)^{2t}} + 2 \sum_{\tau=1}^{N} \sum_{t=1}^{N} \frac{\sigma_t}{((1+k)^t)} \frac{\sigma_\tau}{((1+k)^\tau)} \right]^{1/2}$$

$$= \left[\left(\sum_{t=1}^{N} \frac{\sigma_t}{(1+k)^t} \right)^2 \right]^{1/2} = \sum_{t=1}^{N} \frac{\sigma_t}{(1+k)^t}$$

$$\sigma_{NPV} = \sum_{t-1}^{N} \frac{\sigma_t}{(1+k)^t}. \qquad (70.2b')$$

If the cash flows are mutually independent, then Equation 70.2b' reduces to[2]:

$$\sigma_{NPV} = \sqrt{\sum_{t=1}^{N} \frac{\sigma_t^2}{(1+k)^{2t}}}. \qquad (70.2b)$$

Hillier (1963) combines the assumption of mutual independence and perfect correlation in developing a model to deal with mixed situations. The model as defined in Equation 70.4 can be used to analyze investment proposals in which some of the expected cash flows are closely related, and others are fairly independent. [3]

$$\sigma = \sqrt{\sum_{t=1}^{N} \frac{\sigma_{yt}^2}{(1+k)^2 t} + \sum_{h}^{m} \left(\sum_{t=1}^{N} \frac{\sigma_{zt}^h}{(1+k)^t} \right)^2}, \qquad (70.4)$$

---

[2] Substituting Equation 70.2b and letting $\rho_{\tau t} = 0$, we have

$$\sigma_{NPV} = \left[\sum_{t=1}^{N} \frac{\sigma_t^2}{(1+k)^{2t}} \right]^{1/2}$$

[3] Assume the net cash flow at time t, X_t, is related to the sources as follows

$$X_t = Y_t + Z^{(1)}{}_t + Z^{(2)}{}_t + \ldots + Z^{(m)}{}_t$$

where Y_t, $Z_t^{(1)}, \ldots$, and $Z_t^{(m)}$ are following normal distribution. The random variables for Y_t are mutually independent, $Cov(Y_t, Y_\tau) = 0$, while the random variables for $Z_t^{(1)}, \ldots$, and $Z_t^{(m)}$ are perfectly positive correlated, $Cov(Z_t^{(h)}, Z^{(h)}{}_\tau) = \sigma_{Z_\tau^{(h)}} \sigma_{Z_t^{(h)}}$ for $h = 1, \ldots, m$.
Then variance of NPV is defined as follows:

$$\sigma^2{}_{NPV} = \left[\sum_{t=1}^{N} \frac{\sigma_{Xt}^2}{(1+k)^{2t}} + 2 \sum_{\tau=1}^{N} \sum_{t=1}^{N} \frac{Cov(X_\tau, X_t)}{(1+k)^\tau (1+k)^t} \right]$$

where $\sigma_{Xt}^2 = \sigma_{Yt}^2 + \sigma_{Z_t^{(1)}}^2 + \sigma_{Z_t^{(2)}}^2 + \ldots + \sigma_{Z_t^{(m)}}^2$

$$\begin{aligned} Cov(X_\tau, X_t) &= Cov(Y_\tau + Z_\tau^{(1)} + Z_\tau^{(2)} + \ldots + Z_\tau^{(m)}, \\ & \quad Y_t + Z_t^{(1)} + Z_t^{(2)} + \ldots + Z_t^{(m)}) \\ &= Cov(Y_\tau, Y_t) + Cov(Z_\tau^{(1)}, Z_t^{(1)}) + \ldots \\ & \quad + Cov(Z_\tau^{(m)}, Z_\tau^{(m)}) \end{aligned}$$

Substituting the covariance and variance of Y_t, $Z_t^{(1)}, \ldots$, and $Z_t^{(m)}$, we have

---

where σ_{yt}^2 is the variance for an independent net cash flow in period t, and σ_{zt}^h is the standard deviation for stream h of a perfectly correlated stream of cash flows in period t. It is clear that Equation 70.4 is a combination of Equations 70.2b' and 70.2b''.

Chen and Moore (1982) have generalized Hillier's model by introducing the estimation risk. They argue that Hiller's (1963) approach is unrealistic due to the assumption of parameter certainty. In reality, the parameters of the probability distribution are never known with certainty and thus the capital budgeting decisions based on Hiller's approach may be potentially misleading because this approach ignores the estimation risk. Chen and Moore (1982) in hence extend Hiller's approach with a Bayesian framework which leads to the derivation of a predictive distribution that is not conditioned on unknown parameters. Therefore, the effect of estimation risk in capital budgeting decisions can be eliminated in Chen and Moore (1982) approach. In addition, Wang and Lee (2010) provide the fuzzy real option valuation approach to solve the capital budgeting decisions under uncertainty environment. In Wang and Lee's model framework, the concept of probability is employed in describing fuzzy events and the estimated cash flows are based on the fuzzy numbers which can better reflect the uncertainty in the project. By using a fuzzy real option valuation, the managers can select fuzzy projects and determine the optimal time to abandon the project under the assumption of limited capital budget.

Here is a numerical example to illustrate the model of Equation 70.4. Suppose that a firm is considering the

$$\begin{aligned} \sigma^2{}_{NPV} &= \left[\sum_{t=1}^{N} \frac{\sigma_{Yt}^2 + \sigma_{Z_t^{(1)}}^2 + \sigma_{Z_t^{(2)}}^2 + \ldots + \sigma_{Z_t^{(m)}}^2}{(1+k)^{2t}} \right. \\ & \quad \left. + 2 \sum_{h=1}^{m} \sum_{\tau=1}^{N} \sum_{t=\tau+1}^{N} \frac{\sigma_{Z_\tau^{(h)}} \sigma_{Z_t^{(h)}}}{(1+k)^\tau (1+k)^t} \right] \\ &= \left[\sum_{t=1}^{N} \frac{\sigma_{Yt}^2}{(1+k)^{2t}} + \sum_{h=1}^{m} \left(\sum_{t=1}^{N} \frac{\sigma_{Z_t^{(h)}}^2}{(1+k)^{2t}} \right) + 2 \sum_{h=1}^{m} \sum_{\tau=1}^{N} \right. \\ & \quad \left. \times \sum_{t=\tau+1}^{N} \frac{\sigma_{Z_\tau^{(h)}} \sigma_{Z_t^{(h)}}}{(1+k)^\tau (1+k)^t} \right] \\ &= \left[\sum_{t=1}^{N} \frac{\sigma_{Yt}^2}{(1+k)^{2t}} + \sum_{h=1}^{m} \left[\sum_{t=1}^{N} \frac{\sigma_{Z_t^{(h)}}^2}{(1+k)^{2t}} + 2 \sum_{\tau=1}^{N} \sum_{t=\tau+1}^{N} \right. \right. \\ & \quad \left. \left. \times \frac{\sigma_{Z_\tau^{(h)}} \sigma_{Z_t^{(h)}}}{(1+k)^\tau (1+k)^t} \right] \right] \\ &= \sum_{t=1}^{N} \frac{\sigma_{yt}^2}{(1+k)^{2t}} + \sum_{h=1}^{m} \left(\sum_{t=1}^{N} \frac{\sigma_{zt}^{(h)}}{(1+k)^t} \right)^2 \end{aligned}$$

Table 70.1 Expected cash flow for new product

Year	Source	Expected value of net cash flow (in thousands)	Standard deviation (in thousands)
0	Initial investment	−$600	$50
1	Production cash outflow	−250	20
2	Production cash outflow	−200	10
3	Production cash outflow	−200	10
4	Production cash outflow	−200	10
5	Production outflow – salvage value	−100	15
1	Marketing	300	50
2	Marketing	600	100
3	Marketing	500	100
4	Marketing	400	100
5	Marketing	300	100

introduction of a new product with returns expected over the next 5 years. The probability information for the introduction of the new product is shown in Table 70.1.

Because the product's market reception is uncertain, management feels that, if initial reception exceeds expectations, actual acceptance in later years will also exceed expectations, in approximately the same proportions. For simplicity, it is believed that the net marketing cash flow (sales less marketing and advertising expenses) can be treated as perfectly correlated over time. On the other hand, estimates of the initial investment in the project and the production costs are reasonably reliable, so that any deviation from expectations is assumed to be attributable to random fluctuations. Consequently, initial investment and net production cash flows are regarded as being mutually independent over time. We assume that each of the probability distributions involved can be regarded as normal. If 4% is used as the risk-free rate, the expected value of NPV for the proposal is

$$\overline{NPV} = \sum_{t=0}^{5} \frac{\overline{C}_t}{(1.04)^t} = -600 + \frac{300-250}{(1.04)} + \frac{600-200}{(1.04)^2}$$
$$+ \frac{500-200}{(1.04)^3} + \frac{400-200}{(1.04)^4} + \frac{300-100}{(1.04)^5}$$
$$= \$419.95 = \$420.00.$$

Following Equation 70.4, we can calculate the standard deviation of NPV as:

$$\sigma_{NPV} = \left[50^2 + \frac{20^2}{(1.04)^2} + \ldots + \frac{15^2}{(1.04)^{10}} + \left(\frac{50}{1.04} + \ldots + \frac{100}{(1.04)^5} \right)^2 \right]^{1/2} = \$398.$$

Thus the expected NPV of the proposal is $420 and the standard deviation of the distribution relating to NPV is $398. Using this information, we can express an interval inference for NPV as follows:

$$\Pr(\$420 \pm \$398) = 68.27\%$$
$$\Pr(\$420 \pm (2)(\$398)) = 95.45\%$$
$$\Pr(\$420 \pm (3)(\$398)) = 99.73\%$$

Hillier's approach takes us a long way toward coping with the correlation of cash flows over time, but his method is not always practically applicable. For many investment proposals, cash flows fall into neither of these categories, since in practice they show less than perfect correlation over time. If the correlation is moderate, then the classification suggested by Hillier will not be appropriate. The method suggested by Bonini (1975) and others for handling the problem of moderate correlation is with a series of conditional-probability distributions. Wang and Lee (2010) have expended Bonini's result in terms of fuzzy set and real option approach.

To illustrate the use of conditional-probability approach from Bonini (1975), we refer to Table 70.2, where we consider a project requiring an initial outlay of $10,000 (Column 1). In each of the following time periods (Columns 3, 5, and 7), the cash flow to be received is not known with perfect certainty, but the probabilities associated with each cash flow in each period are assumed to be known (Columns 2, 4, and 6), so that we are dealing with a case of risk, and not strict uncertainty. We note that Columns (4) and (6) are conditional-probability figures, where the later periods' expected cash flows depend highly on what occurs in earlier time periods. Given our cash flow and simple probability estimates for the periods 1, 2, and 3, we find 27 possible joint probabilities (Column 8), each of which corresponds to a cash-flow series. Thus in the uppermost path we find the joint probability 0.015 being associated with a cash flow of $2,000 in Period 1, followed by cash flows of $2,000 and $1,000 in Periods 2 and 3, respectively. This particular path is the worst possible result; in non-discounted dollar terms there is a 50% loss on the investment.

Table 70.2 Illustration of conditional-probability distribution approach

Initial outlay	Initial probability	Net cash flow	Conditional probability	Net cash flow	Conditional probability	Net cash flow	Joint probability
Period 0	P(1)	Period 1	P(2/1)	Period 2	P(3/2,1)	Period 3	probability
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8) = (2) (4) (6)
					0.2	1,000	0.015
			0.25	2,000	0.5	2,000	0.0375
					0.3	3,000	0.0225
					0.2	2,000	0.03
10,000	0.3	2,000	0.5	3,000	0.5	3,000	0.075
					0.3	4,000	0.045
					0.2	3,000	0.015
			0.25	4,000	0.5	4,000	0.0375
					0.3	5,000	0.0225
					0.3	2,000	0.045
			0.3	3,000	0.4	4,000	0.06
					0.3	6,000	0.045
					0.3	4,000	0.06
	0.5	4,000	0.4	5,000	0.4	5,000	0.08
					0.3	6,000	0.06
					0.3	5,000	0.045
			0.3	7,000	0.4	7,000	0.06
					0.3	9,000	0.045
					0.25	4,000	0.0125
			0.25	5,000	0.5	6,000	0.025
					0.25	8,000	0.0125
					0.25	5,000	0.025
	0.2	6,000	0.5	7,000	0.5	7,000	0.05
					0.25	9,000	0.025
					0.25	7,000	0.0125
			0.25	8,000	0.5	9,000	0.025
					0.25	11,000	0.0125

While the primary hurdle in this process is in estimating the cash flows and the probabilities, we recognize that it is the NPV figures we are ultimately interested in. Table 70.3 shows the present value of the cash flows and the net present value of the project for each cash-flow series, where a constant 4% discount rate was employed. At the other end of the spectrum, we find the best possible outcome offers a return $12,945 (the last line of Table 70.3) with a joint probability of 0.0125. When we multiply each joint probability by the expected net present value associated with that probability, we obtain the expected net present value for the project as a whole, there shown to be $2,517.18. Also, from all 27 expected net-present-value figures, we can calculate the variance and the standard deviation for the project as a whole, shown in the lower portion of Table 70.3 as $20,359,090.91 and $4,512.11, respectively.

The use of this form of conditional-probability distribution enables us to take account of the dependence or correlation in the cash flows over time. In the above example, the cash flow in Period 3 depends upon the size of the cash flow in Periods 2 and 1. Given the cash flow in Period 1, the cash

flow in Period 2 can vary within a range, but more of a known range than if we did not know the cash flow in Period 1. Similarly, the cash flows in Period 3 are allowed to vary within a range of values, the range being determined in part by the realized cash flow in the prior period. Most importantly it should be noted that we assume we know what the distribution of each cash-flow figure is, and the probabilities associated with each flow, and, further, that once we make the investment decision we more or less have locked ourselves into the project. In the following section, we relax this latter assumption and allow sequential decisions to be introduced into the conditional-probability decision framework.

70.3 The Decision-Tree Method

A decision-tree approach to capital-budgeting decisions can be used to analyze some investment opportunities involving a sequence of investment decisions over time. The decision tree is an analytical technique used in sequential decisions,

Table 70.3 NPV and joint probability

PVA[a]	NPV	Probability
4,661.2	−5,338.8	0.015

[a]PVA is the net present value of the project for each cash-flow series

where various decision points are studied in relation to subsequent chance events. This technique enables one to choose among alternatives in an objective and consistent manner.

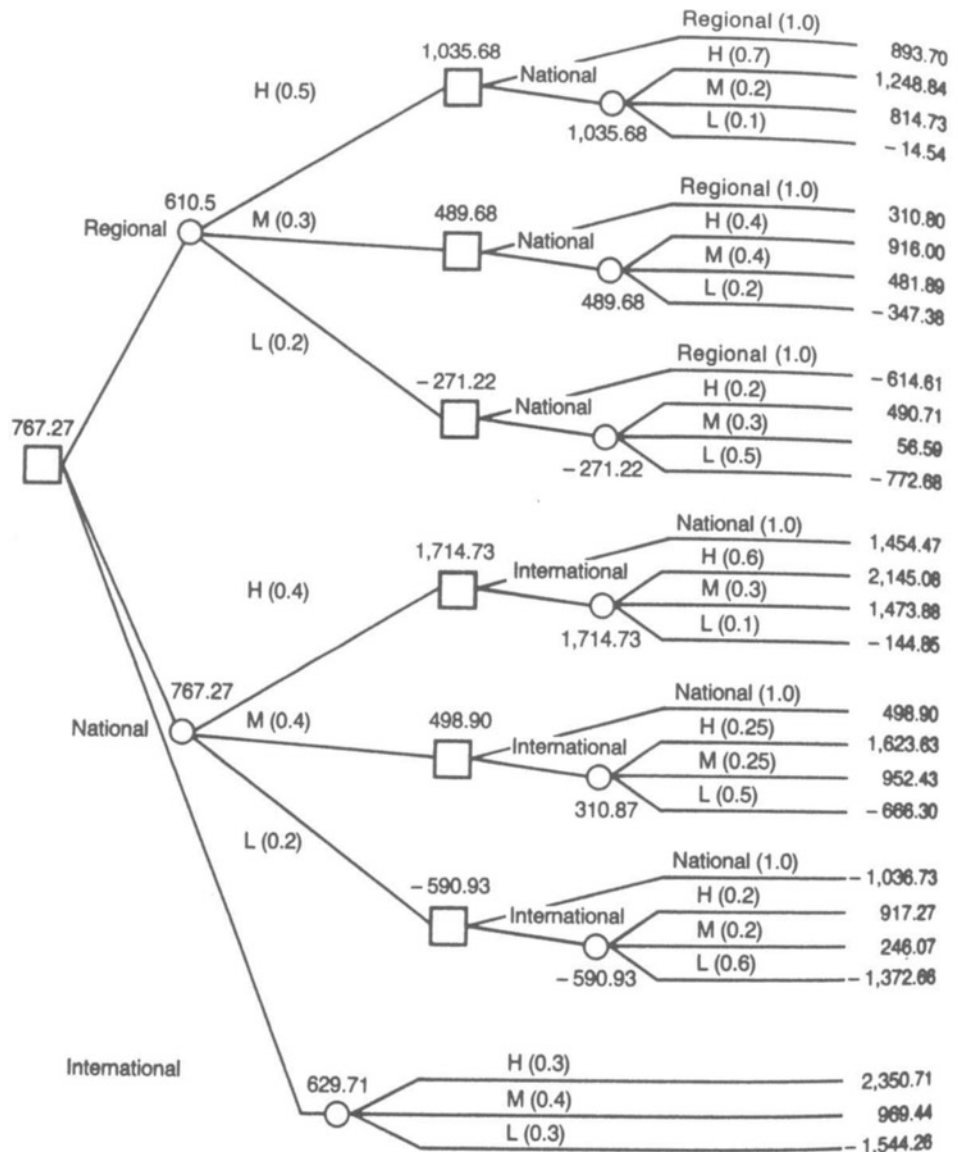
To illustrate this method, let us suppose that a firm is considering the introduction of a new product. The decision process is illustrated graphically by the decision tree shown in Figure 70.1. Initially, it must decide whether to distribute the product either regionally, nationally, or internationally as in Figure 70.1. Regional distribution will require an expenditure of two million dollars for a new plant and the initial market effort. Depending upon demand during the first 2 years, the firm would then decide whether or not to expand to national distribution. Similarly, the firm can distribute nationally at the outset of the project which will require an expenditure of three million dollars in capital expenditure, and then decide whether or not to expand to international distribution. The third alternative is that the firm decides to

distribute its products on an international basis from the very outset, where this alternative would require an initial influx of four million dollars in capital expenditure. In setting up this example, we implicitly assume that the fixed cost of the plant is relatively high, which precludes the possibility of the firm gearing down its operations from an international setting to that of a purely national setting, or from a national effort to one aimed at the smaller regional distribution system. Also, we assume that the scale of the plant is inflexible; the possibility of expanding a regional distribution to one capable of handling the international market is nil.

In Figure 70.1, there are two stages of decisions for regional and national distribution, and one stage of decisions for international distribution. The decision point for each stage is represented by a square. The circles represent chance-event nodes. For example, if the firm decides to distribute internationally at the outset, there is a 0.3 probability that demand for the product will be high, a 0.4 probability that the demand will be more of a moderate level, and a 0.3 probability that the actual demand will be lower than expected. Similar explanations can be followed to interpret probability distributions of demand if the firm decides on regional or national distribution at the initiation of the project.

Table 70.4 shows the expected cash flows and net present values for each possible path of decisions. There are 27 possible series of cash flows for the project. The product's life cycle is assumed to be of a 6-year duration, with no expected salvage value at the end of the life cycle. The expansion decision must be made at the end of year 2, and the cash flows for year 2 reflect the alternative decisions made. Assuming a risk-free rate of 4% prevails, the net present value for each path of decisions is shown in the last column of Table 70.4.

The optimal decision path has the property that, whatever the current state is, the remaining decisions must follow an optimal path. In order to obtain the optimal path of decisions, we solve the problem by working backward. In doing so, we determine the second-stage decision first, that is, the decision of going from regional distribution to national distribution versus continuous regional distribution, or the decision of going from national distribution to international distribution versus that of continuous national distribution. For example, if the firm chooses to distribute regionally and faces high demand for the first 2 years, the firm needs to make the decision pertaining to national distribution. Therefore we need to compare the expected value of net present value for the two alternatives at this decision point. The expected net present value of the combination of regional and national is computed by multiplying the probability of demand by the net present value, then summing over high, moderate, and low demand. The actual computation of this figure is shown as follows:

Fig. 70.1 Decision tree.
Numbers in *parentheses* are
probabilities; numbers *without*
parentheses are NPV expressed in
thousands of dollars


$$NPV = 0.7(\$1,248,840) + 0.2(\$814,730) + 0.1$$
$$\times (-\$14,540)$$
$$= \$1,035,680.$$

Since the expected net present value for national distribution ($1,035,680) is greater than that of continuous regional distribution ($893,700) in the situation of high demand for the first 2 years, the firm should decide to distribute nationally, given that the firm chooses to distribute regionally from the beginning and faces high demand during the first 2 years. In a similar fashion, the expected values of net present values for each second-stage decision can be determined. We note that, given a regional distribution plan at the outset, the firm will opt for national distribution regardless of the demand forthcoming in those first 2 years. From the other

starting point we can see that, if the firm chooses to distribute nationally at the outset, it will expand the facilities to that required for international distribution if demand is either high or low in the first 2 years, but it will continue along its national distribution path if the initial year's demand is judged to be moderate.

The second step to find the optimal path is to calculate the expected net present value for the first stage. In the first stage, the expected net present value for regional is 0.5 ($1,035,680) + 0.3 ($489,680) + 0.2 (−$271,220) = $610,500. The same computation shows that the expected net present value for regional, national, and international distributions are $610,500, $767,270, and $629,710, respectively. Table 70.5 represents the expected net present value for different decision paths. But the analyst should be wary

[a]There are two stages of decisions for regional and national distribution. The interaction part would be the combination of regional and national or the combination of national and international. Therefore, there are 18 possible series of cash flows in the interaction part and 9 possible series of cash flows in one stage of decisions for the project

Table 70.5 Expected value and standard deviation of NPV in the first stage

Decision variables for the first stage	Expected NPV[a]	Standard deviation[a]	Coefficient of variation
Regional	610.50	666.98	1.093
National	767.27	1067.20	1.3909
International	629.71	1533.80	2.4357

[a]Expressed in thousands of dollars

of using these figures exclusively, since the risks of the different decision paths are also important. The expected net present values and the associated standard deviations for the preceding example are shown as:

Since national distribution has both a higher expected net present value and a lower expected standard deviation than the international distribution, the national distribution plan should dominate the international plan, assuming that the management displays risk aversion. The choice between the regional and national distribution systems is less clear, though; while it is true that the national-distribution alternative carries a higher expected net present value, it also displays a greater degree of potential variability, both in absolute standard deviation and in relative (coefficient-of-variation) terms, than the regional alternative. Thus, the final decision rests on the risk attitudes of management.

Nonetheless, we find that this method, where sequential decisions are allowed, involves a slightly different type of risk as the firm is not locked into any particular distribution method for the project, unless, of course, it initially decides to distribute internationally. Thus the risk of being locked into a project is less, though the variability of the cash flows

Table 70.6 Variables for simulation

Variables		Range
1. Market size (units)	(VMARK)	2,500,000–3,000,000
2. Selling price ($/unit)	(PRICE)	40–60
3. Market growth	(GROW)	0–5%
4. Market share	(SMARK)	10–15%
5. Total investment required ($)	(TOINV)	8,000,000–10,000,000
6. Useful life of facilities (years)	(KUSE)	5 – 9
7. Residue value of investment ($)	(RES)	1,000,000–2,000,000
8. Operating cost ($)	(VAR)	30–45
9. Fixed cost ($)	(FIX)	400,000–500,000
10. Tax rate	(TAX)	40%
11. Discount rate	(DIS)	12%

Notes: (a) Random numbers from Wonnacott and Wonnacott (1990) are used to determine the value of the variable for simulation
(b) Useful life of facilities is an integer

Random number	Year
00–19	5
20–39	6
40–59	7
60–79	8
80–99	9

over time or across distribution methods may be greater when sequential decisions are allowed, and the computational difficulty can be seen to grow as well.

70.4   Simulation Analysis

Simulation is another approach to confronting the problems of capital budgeting under uncertainty. Because uncertainty associated with capital budgeting is not restricted to one or two variables, every variable relevant in the capital-budgeting decision can be viewed as a random variable. Facing so many random variables, it may be impossible to obtain tractable results from an economic model. Simulation is a useful tool designed to deal with this problem, and is the closest we can get to modeling in cases of uncertainty.

The following example utilizes the simulation model developed by Hertz (1964). Here we consider a firm that intends to introduce a new product where the 11 input factors thought to determine project value are shown in Table 70.6. Of these inputs, variables 1–9 are specified as random variables with the ranges listed in Table 70.6. It would be possible to add a random element to variables 10 and 11, but the computational complexity and the insights gained do not justify the effort.

Also, for ease of modeling, we chose to implement the uniform distribution as that describing the probability of any particular outcome in that specified range. By using a set range

for each of the nine random variables, we are not actually allowing the probabilities of each possible outcome to vary, but the spirit of varying probabilities is imbedded in the simulation approach. One further restriction is made in the model, that being that the life of the facilities is restricted to an integer value, with the range as specified at the bottom of Table 70.6. The uniform distribution density function can be written as

$$f_x = \begin{cases} \frac{1}{\beta - \alpha} \\ 0 \end{cases} \quad \text{elsewhere}$$

where ß is the upper bound on the variable value and α is the lower bound. With this in mind, we note the way in which the values are assigned. For each successive input variable, a random-number generator selects a value from 01 to 00 (where 00 is the proxy for 100 using a two-digit random-number generator) and then translates that into a variable value by taking account of the specified range and distribution of the variable value by taking account of the specified range and distribution of the variable in question.

Table 70.7 shows ten times simulation results and the expected value of NPV is the average of the NPV in each simulation. For each simulation, nine random numbers are selected. Because the useful life of facilities is restricted to integer values, we impose the following correspondence between random numbers and useful life of facilities in Table 70.7. From these random numbers a set of values for the nine key factors are created. For example, the first set of random numbers as shown in Table 70.7 is (39, 73, 72, 75, 37, 02, 87, 98, and 10). The value of variables for the first simulation can be obtained as follows:

Market

$$\text{size:} 2,500,000 + \frac{(39)(3,000,000 - 2,500,000)}{(100)} = 2,695,000.$$

Selling price: $40 + \frac{(73)(\$60 - \$40)}{(100)} = \$54.6$.

Market growth: $0.00 + \frac{(72)(0.05 - 0.00)}{(100)} = 0.036 \ or \ 3.6\%$.

Market share: $0.10 + \frac{(75)(0.15 - 0.10)}{(100)} = 0.1375 \ or \ 12.75\%$.

Total   investment   required:
$\$8,000,000 + \frac{(37)(\$10,000,000 - \$8,000,000)}{(100)} = \$8,740,000$.

Useful life of facilities: 5 years

Residue   value   of   investment:
$\$1,000,000 + \frac{(87)(\$2,000,000 - \$1,000,000)}{(100)} = \$1,870,000$.

Operating cost: $\$30 + \frac{(98)(\$45 - \$30)}{(100)} = \$44.7$

Fixed cost: $\$400,000 + \frac{(10)(\$500,000 - \$400,000)}{(100)} = \$410,000$.

Similar computations can be used to calculate the values of all variables except the useful life of the facilities.

For each simulation, a series of cash flows and the net present value can be calculated by using the following formula:

$$(70.5)$$

$$\text{EBIT}_t = (\text{Sales Volume})_t(\text{Selling Price} - \text{Operating Cost}) - (\text{Fixed Cost})$$

$$(70.6)$$

$$(\text{Cash Flow})_t = (\text{EBIT})_t(1 - \text{Tax Rate}) \qquad (70.7)$$

$$NPV = \sum_{t=1}^{Useful\ life} \frac{(\text{Cash Flow})_t}{(1 + \text{Discount Rate})^t} - I_0 + \frac{(\text{RES})_{Useful\ life}}{(1 + \text{Discount Rate})^{Useful\ life}} \qquad (70.8)$$

where t represents the t th year, discount rate is 12%, tax rate is 40%, I_0 is total investment required, and RES is the residue value of investment listed on Table 70.7.

The results in terms of cash flow for each simulation are listed in Table 70.8 with each period's cash flows shown separately. The NPVs for each simulation can be found under the input values listed in Table 70.7. From these NPV figures we can again calculate a mean NPV figure and variance and standard deviation, from which we can analyze the risk and the return profile of the project.

Furthermore, if we choose to change the range or the distribution of the random variables, sensitivity analysis can be performed to investigate the impact of the change in an input factor on the risk and return of the investment project. Also, by way of the sensitivity-analysis approach, we in essence decompose the uncertainty involved in undertaking of any project, thereby highlighting exactly what the decision maker should be primarily concerned with: forecasting in terms of those variables critical to the analysis. The information obtained from the simulation analysis will be valuable in allowing the decision maker to more accurately evaluate risky capital investments.

Conclusion

The statistical distribution, decision-tree, and simulation methods are three alternative approaches that are available to deal with the problem of capital budgeting under uncertainty. These methods have explicitly utilized the concepts of probability distributions and statistical distributions to carry out the analysis.

The backward-induction process and the basis of dominance are two important criteria used in the decision-tree method of capital budgeting. The basic concepts used in simulation analysis are almost identical to that of the statistical distribution method of capital budgeting. The simulation method uses the information associated with net cash-flow, useful life of facilities, and salvage value, to estimate the distribution of net present value of cash flows. The simulation method of capital budgeting explicitly uses the distributions of the inputs related to market analysis, investment cost analysis, and the operating and fixed costs anticipated to simulate the distribution of NPV. The simulation method can also explicitly incorporate the detailed information into the decision process.

In sum, the stochastic methods discussed in this paper are generally more objective and general than the traditional capital budgeting methods under the assumption of certainty in cash flows.[4] If there is only a single accept-reject decision at the outset of the project, then the decision maker can use either statistical distribution methods or simulation methods. If investment opportunities involve a sequence of decisions over time, then a decision-tree method can be used to perform the analysis.

Valuation of Interest Tax Shields

71

Michael Dothan

Abstract

Assessing financing effects, such as tax benefits of debt, is an important part of financial analysis and valuation. This chapter describes the frameworks and valuation formulas of Modigliani-Miller, Miles-Ezzell, modified Miles-Ezzell, Modigliani-Miller with growth, Fernandez, and other related setups. In addition, the chapter examines recent dynamic models that value interest tax shields in the context of flexible financing strategies. The chapter starts with two summary tables that list notation, definitions, and formulas for some discrete-time valuation models. Because of the diversity of views on the appropriate discount rate for interest tax shields, I present a short derivation of the Miles-Ezzell formula. The last part of the chapter reviews recent dynamic valuation models of interest tax shields, including the application of barrier options to analyzing the effects of flexible financing strategies, and presents a summary that compares the valuation outcomes of the various models.

71.1 Introduction

Enterprise value of a leveraged firm is the sum of equity value and debt value. In standard financial models, enterprise value can be computed either by discounting unleveraged free cash flows at the weighted average cost of capital (WACC), or by adding the effects of financing strategies, such as the value of interest tax shields, to the unleveraged firm value that represents operating decisions. Interest tax shields are an important part of enterprise value, Graham [2000] estimates the tax benefits of debt realized by a typical firm at 9.7% of enterprise value, and Kemsley and Nissim [2002] estimate that the average value of interest tax shields is 10% of enterprise value. For high-debt firms, acquired by private equity firms in a leveraged buyout,

Kaplan and Strömberg [2009] estimate the value of interest tax shields at 10–20% of enterprise value.

The process of separating operating and financing effects, proposed by Modigliani and Miller [1963] and Myers [1974], is known as the adjusted present value (APV) method of valuation. Luehrman [1997] promotes the view that APV is the better alternative. Whereas WACC requires only one discounting operation rather than two or more, it is not as good as APV at taking care of the effects of financing strategies. In addition, APV is better at unbundling and making visible the components of value, and can be customized according to specific circumstances and managers' needs. The popular corporate finance textbook Brealey et al. [2011] echoes those sentiments, saying that the APV method "gives the financial manager an explicit view of the factors that are adding or subtracting value." Koller et al. [2010], through several editions of their advanced book on valuation, are also strong proponents of separating the effects of operating and financing strategies.

Booth [2002] contends that the APV method is not always consistent with the WACC method, and demurs at

the assumption of constant market leverage that characterizes the so-called Miles-Ezzell formula, presented here in Section 71.3.3. I will argue in Section 71.5 that recently developed valuation models with dynamic debt policies allow us to attenuate those concerns.

The recent models exploit a link between barrier options and the value of interest tax shields. Barrier options come to life, expire, and/or make a cash payoff contingent on a barrier event, such as EBIT hitting a specified barrier for the first time. The link between barrier options and interest tax shields arises in explicit modeling of default and refinancing, with the associated loss or increase of interest tax shields.

I start this chapter with two summary tables that list notation, definitions, and formulas for some discrete-time valuation models. Next, I describe two influential models of interest tax shields: Modigliani-Miller and Miles-Ezzell. Because of the diversity of views on the appropriate discount rate for interest tax shields, I present a short derivation of the Miles-Ezzell formula. Subsequently, I consider several alternative models with fixed debt or leverage ratio. The last part of this chapter reviews recent dynamic valuation models of interest tax shields, including the application of barrier options to analyzing the effects of flexible financing strategies, and presents a summary that compares the valuation outcomes of the various models.

71.2   Notation, Definitions, and Formulas

The items in Tables 71.1 and 71.2 refer to a perpetual model. Time index t is an integer $t \geq 0$. Some table entries are indexed by $t + 1$ rather than t for convenience, because that is how they appear in the formulas. Regardless of the notation, all such entries are defined for every discrete-time starting at 0.

It is well-known that the weighted average cost of capital in line 19 of Table 71.1 is the suitable discount rate for the unleveraged free cash flow FCF_{t+1} to obtain leveraged enterprise value at time t, as implied by line 18 of Table 71.1. The calculation is straightforward, multiply line 15 by $\frac{1}{1+L_t}$, multiply line 16 by $\frac{(1-T_C)L_t}{1+L_t}$, and add, then use lines 12 and 18 to get line 19.

The technical meaning of conditioning information $\mathcal{F}_t$ in line 14 is the σ-field of events that are decidable at time t. Coupon payment in line 5 is random, and reflects the possibility of default. The pricing kernel in line 21 of Table 71.1 adjusts future cash flows and values for risk-neutral valuation. In particular, the conditional expectation of the pricing kernel is the risk-free discount factor, as shown in line 22.

The stationary or steady-state model in Table 71.2 is characterized by a constant mean growth rate g and fixed

market leverage ratio L. Fixed market leverage ratio means that, as enterprise value evolves over time, the amount of debt is rebalanced or adjusted at each discrete-time point to maintain a fixed ratio of market debt value to market equity value, or, equivalently, of market debt value to market enterprise value.

The formulas in lines 3 and 4 of Table 71.2 represent standard valuation of perpetual growth annuities. The significance of the adjustment factor in line 5 is due to its part in the relationship between WACC and required asset return in line 6, which leads to the valuation formula of interest tax shields in line 8, as shown in Section 71.3.3. Lastly, it is important to recognize that notation in papers cited in this chapter varies, and, in particular, some authors define the market leverage ratio as $\frac{D_t}{W_t}$, which corresponds to $\frac{L_t}{1+L_t}$ in our notation.

71.3   Two Influential Models

Two influential works that analyze the value of interest tax shields are the combination of Modigliani and Miller [1958, 1963], and the combination of Miles and Ezzell [1980, 1985].

71.3.1   Modigliani-Miller Formula

The Modigliani and Miller [1958, 1963] model is set in discrete time, debt is perpetual, the value of debt is fixed, and the cost of debt is constant. This framework corresponds to the unleveraged free cash flow fluctuating around a constant level $FCF_{t+1} = FCF_t(1 + \varepsilon_{t+1})$, with $E(\varepsilon_{t+1}|\mathcal{F}_t) = 0$, and $D_t = D_0$. It is important to recognize that the model assumes that interest expense C_t is non-random, so that $r_{D,t} = \frac{C_{t+1}}{D_t} = \frac{C_{t+1}}{D_0}$ is a constant $r_{D,t} = r_D$. The model does not deduct the value of deadweight default cost. Starting with the recursive equation for a perpetual annuity

$$VTS_t = \frac{T_c r_D D_0}{1+r_D} + \frac{VTS_t}{1+r_D} \tag{71.1}$$

and solving for VTS$_t$, we get

$$VTS_t = \frac{T_c r_D D_0}{r_D} = T_c D_0 \tag{71.2}$$

Notably, Equation 71.2 is valid only if $r_D > 0$. Otherwise, if $r_D = 0$, Equation 71.1 is a tautology, and has nothing to say about the value of interest tax shields. We can, however, use

Table 71.1 Notation, definitions, and formulas for discrete-time valuation models

1	Market equity value	S_t
2	Market debt value	D_t
3	Market leveraged enterprise value	$W_t = S_t + D_t$
4	Market unleveraged firm value	V_t
5	Coupon or interest expense	C_{t+1}
6	Corporate tax rate	T_C
7	EBIT	X_{t+1}
8	Invested capital	U_t
9	Return on invested capital (ROIC)	$R_{t+1} = \frac{(1-T_C)X_{t+1}}{U_t}$
10	Unleveraged free cash flow	$FCF_{t+1} = (1 - T_C)X_{t+1} - (U_{t+1} - U_t)$
11	Leveraged free cash flow	$FCF^\star_{t+1} = FCF_{t+1} + T_C C_{t+1}$
12	Leveraged equity cash flow	$ECF^\star_{t+1} = FCF_{t+1} - (1 - T_C)C_{t+1} + D_{t+1} - D_t$
13	Risk-free or cash rate	r_F
14	Conditioning information	$\mathcal{F}_t$
15	Required equity return or cost of equity	$r_{S,t} = \frac{E\left(ECF^\star_{t+1} + S_{t+1}|\mathcal{F}_t\right) - S_t}{S_t}$
16	Cost of debt	$r_{D,t} = \frac{E(C_{t+1}|\mathcal{F}_t)}{D_t}$
17	Market leverage ratio	$L_t = \frac{D_t}{S_t}$
18	Weighted average cost of capital (WACC)	$r_{W,t} = \frac{E(FCF_{t+1} + W_{t+1}|\mathcal{F}_t) - W_t}{W_t}$
19	Formula for weighted average cost of capital (WACC)	$r_{W,t} = \frac{r_{S,t} + \left(1 - T_C\right)L_t r_{D,t}}{1 + L_t}$
20	Required asset return or cost of unleveraged equity	$r_{A,t} = \frac{E(FCF_{t+1} + V_{t+1}|\mathcal{F}_t) - V_t}{V_t}$
21	Pricing kernel	z_{t+1}
22	Risk-free discount factor	$\frac{1}{1+r_F} = E(z_{t+1}|\mathcal{F}_t)$
23	Market unleveraged firm value using pricing kernel	$V_t = E[(FCF_{t+1} + V_{t+1})z_{t+1}|\mathcal{F}_t]$
24	Market leveraged enterprise value using pricing kernel	$W_t = E\left[\left(FCF^\star_{t+1} + W_{t+1}\right)z_{t+1}|\mathcal{F}_t\right]$

Table 71.2 Notation, definitions, and formulas for discrete-time stationary valuation models

1	Fixed mean growth	g
2	Fixed market leverage ratio	$L = \frac{D_t}{S_t}$
3	Market unleveraged firm value	$V_t = \frac{FCF_t(1+g)}{r_A - g}$
4	Market leveraged enterprise value	$W_t = \frac{FCF_t(1+g)}{r_W - g}$
5	Adjustment factor	$\lambda = \frac{T_C r_D}{1 + r_D}$
6	Formula for WACC in terms of required asset return	$1 + r_W = \left(1 - \frac{\lambda L}{1+L}\right)(1 + r_A)$
7	Formula for required asset return	$r_A = \frac{r_S + (1-\lambda)L r_D}{1 + (1-\lambda)L}$
8	Valuation of interest tax shields	$VTS_t = \frac{T_C r_D D_t}{r_A - g}\,\frac{1 + r_A}{1 + r_D}$

general financial considerations to conclude that an interest-free loan generates zero interest tax shields. Therefore, a more precise form of Equation 71.2 is

$$VTS_t = \begin{cases} T_C D_0 & \text{if } r_D > 0 \\ 0 & \text{if } r_D = 0 \end{cases} \tag{71.3}$$

I return to this issue in Section 71.4.

71.3.2 Example

The firm's fixed debt is $D_t = D_0 = 250$, constant cost of debt is $r_D = 8\%$, and the corporate tax rate is $T_C = 25\%$. Using Equation 71.3 we get $VTS_t = 62.50$.

71.3.3 Miles-Ezzell Formula

The model of Miles and Ezzell [1980, 1985] is set in discrete time, debt is perpetual, and market leverage ratio is fixed. This framework corresponds to the stationary model of unleveraged free cash flow fluctuating around a growing level $FCF_{t+1} = FCF_t(1 + g + \varepsilon_{t+1})$, with noise ε_t drawn from a fixed distribution, $E(\varepsilon_{t+1}|\mathcal{F}_t) = 0$, and constant market leverage $L_t = L_0$, implying that $r_{S,t} = r_S$, $r_{D,t} = r_D$, and $r_{A,t} = r_A$. The model does not deduct the value of deadweight default cost. The Miles-Ezzell formula is

$$VTS_t = \frac{T_C r_D D_t}{r_A - g}\,\frac{1 + r_A}{1 + r_D} \tag{71.4}$$

Equation 71.4 follows from the relationship between weighted average cost of capital and required asset return in line 6 of Table 71.2

$$1 + r_W = \left(1 - \frac{\lambda L}{1 + L}\right)(1 + r_A) \qquad (71.5)$$

I present a short verification of the Miles-Ezzell formula from Equation 71.5 and, in Section 71.3.5, offer a short derivation of Equation 71.5 based on Arzac and Glosten [2005]. Combining Equation 71.5 with the definition of the constant market leverage ratio in line 2 of Table 71.2, and multiplying by W_t implies

$$(r_W - r_A)W_t = -\lambda D_t(1 + r_A) \qquad (71.6)$$

From line 0 of Table 71.2 we have

$$(r_W - g)W_t = FCF_t(1 + g) \qquad (71.7)$$

Subtracting Equation 71.6 from Equation 71.7, diving by $r_A - g$, and using the formula for the adjustment factor in line 5 of Table 71.2, yields

$$W_t = \frac{FCF_t(1 + g)}{r_A - g} + \frac{T_c r_D D_t}{r_A - g} \frac{1 + r_A}{1 + r_D} \qquad (71.8)$$

The first term on the right side of Equation 71.8 is the value of the unleveraged firm, and the second term is the value of interest tax shields, as presented in Equation 71.4. It is important to note that even with expected zero growth, the Modigliani-Miller and Miles-Ezzell valuation formulas produce different results. Indeed, substituting $g = 0$ in Equation 71.4, we get

$$VTS_t = \frac{T_c r_D D_t}{r_A} \frac{1 + r_A}{1 + r_D} \qquad (71.9)$$

Because $r_D < r_A$, we get a value that is less than the Modigliani-Miller value of $T_c D_t$. With the same assumption about zero mean growth, this difference is due to different assumptions about the cost of debt.

An important factor in the application of the Miles-Ezzell formula is the availability of required asset return r_A. To the extent that we accept the stationary model as a rough approximation to the reality of at least some firms, we can employ the formula in line 0 of Table 71.2 to estimate r_A, using the same inputs as in the calculation of the weighted average cost of capital (WACC) r_W. I will return to the realism of the stationary model and a proposed relaxation of some of its assumptions in Section 71.5.

An important feature of the Miles-Ezzell formula in Equation 71.4 is that it satisfies the recursive valuation equation

$$VTS_t = \frac{T_c r_D D_t}{1 + r_D} + \frac{1 + g}{1 + r_A} VTS_t \qquad (71.10)$$

This validates the notion that next year's tax savings should be discounted at the cost of debt, whereas all subsequent tax savings should be discounted at the required asset return. The Miles-Ezzell formula is favored by Lewellen and Emery [1986], Taggart [1991], Arzac and Glosten [2005], and Brealey et al. [2011]. Interestingly, Harris and Pringle [1985], Ruback [1995, 2002], Cooper and Nyborg [2006], and Farber et al. [2006] present instead a modified Miles-Ezzell formula

$$VTS_t = \frac{T_c r_D D_t}{r_A - g} \qquad (71.11)$$

A possible reconciliation is offered by Taggart [1991], Arzac and Glosten [2005], and Brealey et al. [2011], who observe that the Miles-Ezzell formula is valid for discrete rebalancing of debt to maintain a fixed market leverage ratio, whereas the modified Miles-Ezzell formula is valid for continuous rebalancing of debt, with r_D, r_A, and g representing continuous-time cost of debt, required asset return, and mean growth, respectively.

71.3.4 Example

Debt value is $D_t = 250$, cost of debt is $r_D = 8\%$, mean growth rate is $g = 7\%$, required asset return is $r_A = 12\%$, and corporate tax rate is $T_C = 25\%$. Applying Equation 71.4 we get $VTS_t = 103.70$. For comparison, using Equation 71.11 to compute the modified Miles-Ezzell value we get $VTS_t = 100.00$. The value of interest tax shields is larger here than in the Modigliani-Miller Example 71.3.2 because of different assumptions about the cost of debt and the presence of positive mean growth.

71.3.5 Weighted Average Cost of Capital and Required Asset Return

The preceding validation of the Miles-Ezzell formula rests on the relationship in Equation 71.5. To derive Equation 71.5, notice that from line 3 of Table 71.2 the unleveraged firm value V_{t+1} is proportional to the free cash flow FCF_{t+1}, with the proportionality constant $\frac{1+g}{r_A-g}$. Therefore

$$\begin{aligned} V_t &= E[(FCF_{t+1} + V_{t+1})z_{t+1}|\mathcal{F}_t] \\ &= \frac{1 + r_A}{r_A - g} E(FCF_{t+1}z_{t+1}|\mathcal{F}_t) \end{aligned} \qquad (71.12)$$

Similarly, from line 4 of Table 71.2, the leveraged enterprise value W_{t+1} is proportional to unleveraged free cash flow FCF_{t+1}, with the proportionality constant $\frac{1+g}{r_W-g}$. Therefore, starting with leveraged free cash flow and using line 11 of Table 71.1

$$
\begin{aligned}
W_t &= E\left[\left(FCF^\star_{t+1} + W_{t+1}\right)z_{t+1}|\mathcal{F}_t\right] \\
&= E[(FCF_{t+1} + T_c C_{t+1} + W_{t+1})z_{t+1}|\mathcal{F}_t] \\
&= \frac{1+r_W}{r_W-g}E(FCF_{t+1}z_{t+1}|\mathcal{F}_t) + E(T_c C_{t+1}z_{t+1}|\mathcal{F}_t)
\end{aligned}
$$
(71.13)

The second term on the right is

$$
E(T_c C_{t+1}z_{t+1}|\mathcal{F}_t) = \frac{T_c r_D D_t}{1+r_D} = \frac{T_c r_D W_t}{1+r_D}\frac{L}{1+L}
$$
(71.14)

Using the notation for the adjustment factor in line 5 of Table 71.2, and combining Equations 71.13 and 71.14, we get

$$
W_t\left(1 - \frac{\lambda L}{1+L}\right) = \frac{1+r_W}{r_W-g}E(FCF_{t+1}z_{t+1}|\mathcal{F}_t)
$$
(71.15)

Dividing Equation 71.15 by Equation 71.12

$$
\frac{W_t}{V_t}\left(1 - \frac{\lambda L}{1+L}\right) = \frac{1+r_W}{1+r_A}\frac{r_A-g}{r_W-g}
$$
(71.16)

From lines 3 and 4 of Table 71.2 we have $\frac{W_t}{V_t} = \frac{r_A-g}{r_W-g}$, and Equation 71.5 follows.

71.4 Other Models with Fixed Debt or Leverage Ratio

If we modify the assumptions of Modigliani and Miller [1963] to allow debt to grow at a fixed mean rate g, and assume that the cost of debt r_D remains constant, we can formally write a version of Equation 71.1 with growth

$$
VTS_t = \frac{T_c r_D D_t}{1+r_D} + \frac{1+g}{1+r_D}VTS_t
$$
(71.17)

The solution of Equation 71.17 represents a Modigliani-Miller formula with growth

$$
VTS_t = \frac{T_c r_D D_t}{r_D-g}
$$
(71.18)

The formula in Equation 71.18 is favored by Myers [1974], Sick [1990], Luehrman [1997], Fieten et al. [2005], and Damodaran [2006]. It rests on the heuristic that the uncertainty of tax savings of debt is the same as the uncertainty of

debt. There is, however, a counter-argument to this heuristic, which says that the two risks are not the same because default brings the tax savings of debt to zero, but debt frequently has positive recovery rate at default. The Miles-Ezzell formula delivers a refinement of the valuation technique in Equation 71.18.

71.4.1 Example

Debt value is $D_t = 250$, constant cost of debt is $r_D = 8\%$, mean growth is $g = 7\%$, and the corporate tax rate is $T_C = 25\%$. Using Equation 71.18 we get $VTS_t = 500$.

In the context of the discrete-time stationary model, Fernandez [2004] and Roncaglio and Zanetti [2004] derive a valuation formula of interest tax shields that differs from the Miles-Ezzell formula and states instead that

$$
VTS_t = \frac{T_c r_A D_t}{r_A-g}
$$
(71.19)

Because the cost of debt r_D is less than the required asset return r_A, valuation produced by Equation 71.19 is greater than valuation produced by the Miles-Ezzell formula. Arzac and Glosten [2005] and Cooper and Nyborg [2006] question the derivation of Equation 71.19 in both Fernandez [2004] and Roncaglio and Zanetti [2004]. Both Arzac and Glosten [2005] and Cooper and Nyborg [2006] contend that Fernandez [2004] assumes constant market leverage ratio but uses Equation 71.2 instead of Equation 71.9 in his derivation. Fernandez [2005] agrees, and contends that Equation 71.19 is suitable for valuation of interest tax shields when the firm maintains constant leverage ratio in book value terms, because then changes in the amount of debt have the same risk as unleveraged free cash flows. Arzac and Glosten [2005] derive a valuation equation which represents an additive adjustment to the Modigliani-Miller formula. From line 0 of Table 71.1

$$
T_c C_{t+1} = \frac{T_c}{1-T_c}\left(FCF_{t+1} - ECF^\star_{t+1} + D_{t+1} - D_t\right)
$$
(71.20)

Therefore

$$
\begin{aligned}
VTS_t &= \sum_{s\geq t} E(T_c C_{s+1}z_{s+1}|\mathcal{F}_t) = \frac{T_c}{1-T_c} \\
&\sum_{s\geq t} E\left[FCF_{s+1}z_{s+1} - ECF^\star_{s+1}z_{s+1} + (D_{s+1}-D_s)z_{s+1}|\mathcal{F}_t\right] \\
&= \frac{T_c}{1-T_c}(V_t - S_t) + \frac{T_c}{1-T_c}\sum_{s\geq t}E[(D_{s+1}-D_s)z_{s+1}|\mathcal{F}_t]
\end{aligned}
$$
(71.21)

Taking into account that $V_t - S_t = D_t - VTS_t$, and solving Equation 71.21 for VTS_t, we get the formula

$$VTS_t = T_C D_t + T_C \sum_{s \geq t} E[(D_{s+1} - D_s)z_{s+1}|\mathcal{F}_t] \quad (71.22)$$

Applying Equation 71.22 to the Miles-Ezzell framework produces the Miles-Ezzell formula

$$\begin{aligned} VTS_t &= T_C D_t + T_C D_t \\ &\sum_{s \geq t} \left[\left(\frac{1+g}{1+r_A} \right)^{s-t+1} - \frac{1}{1+r_D} \left(\frac{1+g}{1+r_A} \right)^{s-t} \right] \\ &= \frac{T_C r_D D_t}{r_A - g} \frac{1+r_A}{1+r_D} \end{aligned}$$

$$(71.23)$$

Arzac and Glosten [2005] show that Roncaglio and Zanetti [2004] get Equation 71.19 when they disregard, in Equation 71.22, the lack of systematic risk between debt at time, t represented by D_t, and the pricing kernel at time $t + 1$, represented by z_{t+1}

$$\begin{aligned} VTS_t &= T_C D_t + T_C D_t \\ &\sum_{s \geq t} \left[\left(\frac{1+g}{1+r_A} \right)^{s-t+1} - \frac{1}{1+r_A} \left(\frac{1+g}{1+r_A} \right)^{s-t} \right] \\ &= \frac{T_C r_A D_t}{r_A - g} \end{aligned}$$

$$(71.24)$$

71.4.2 Example

Debt value is $D_t = 250$, required asset return is $r_A = 12\%$, mean growth is $g = 7\%$, and the corporate tax rate is $T_C = 25\%$. Using Equation 71.19 we get $VTS_t = 150$.

Liu [2009] questions the valuation framework of Modigliani and Miller [1963], arguing that because Equation 71.2 is invalid when the debt is interest-free, or when the firm has infinite leverage ratio L_t, the Modigliani-Miller formula does not value interest tax shields correctly anywhere in the Modigliani-Miller framework. Instead, Liu [2009] proposes a valuation method, that he calls the slicing approach, of decomposing the Modigliani-Miller formula into earned and unearned parts, with the earned part being $\frac{r_{D,t}}{R_t} T_C D_t$, where R_t is return on invested capital. Qi [2011] delivers a critique of the arguments in Liu [2009], contending that the issue of correctness of Equation 71.2 in the Modigliani-Miller framework is resolved by replacing Equation 71.2 with Equation 71.3, that the special case of infinite leverage does not invalidate Equation 71.2, and that the slicing approach is not consistent with prevailing models of the relationship between risk and return.

71.5 Models with Dynamic Debt Policies

The general problem with valuing interest tax shields is that the risk profile of tax shields is different from the risk profile of either debt or equity. Interest tax shields are less variable than equity cash flows, and expire when debt may still have positive recovery rate at default. In addition, fixed leverage ratio is not a very realistic assumption: In bad times the firm would have to prepay debt and issue new stock at a low price.

The fixed market leverage ratio assumption requires a financing strategy that makes the value of debt a constant multiple of unleveraged free cash flow FCF_t. Indeed, from lines 0 and 0 of Table 71.2

$$D_t = \frac{1+g}{r_W - g} \frac{L}{1+L} FCF_t \quad (71.25)$$

Grinblatt and Liu [2008] present a general, continuous-time valuation framework for interest tax shields when unleveraged free cash flow is a general Ito diffusion process, and financing strategy makes the value of debt a linear combination of real powers of unleveraged free cash flow, such as $D_t = d_0 + d_{\frac{1}{3}} FCF_t^{\frac{1}{3}} + d_{\frac{1}{2}} FCF_t^{\frac{1}{2}} + d_1 FCF_t + d_2 FCF_t^2$. Apart from simple special cases, valuation of interest tax shields requires a numerical solution of a system of ordinary differential equations. The paper does not explicitly model the loss of interest tax shields upon default.

Couch et al. [2012] use barrier option methodology to model explicitly the loss of interest tax shields associated with default, and to allow more flexible financing strategies than the constant rebalancing of debt to maintain a fixed leverage ratio. Recall that the stationary discrete-time model in Section 71.3.3 specifies an unleveraged free cash flow that fluctuates around a growing level $FCF_{t+1} = FCF_t(1 + g + \varepsilon_{t+1})$, with noise ε_t drawn from a fixed distribution, and $E(\varepsilon_{t+1}|\mathcal{F}_t) = 0$. The corresponding continuous-time process that they use for EBIT X_t is an Ito diffusion with constant coefficients, where B_t is a standard Brownian motion

$$dX_t = X_t(gdt + \sigma dB_t) \quad (71.26)$$

As before, expected EBIT grows at a constant rate g, but now there is a second constant parameter σ, which captures the volatility of EBIT, and is commonly considered a measure of business risk.

As in Fischer et al. [1989] and Goldstein et al. [2001], this continuous-time framework can capture an asymmetric financing strategy and explicitly model the possibility of loss of interest tax shields when the firm defaults. Specifically, the firm issues debt with coupon or interest expense C,

but does not maintain a fixed leverage ratio. Financing policy is asymmetric: The firm increases the amount of debt at random times when EBIT X_t increases by a specified growth factor, but does not reduce the amount of debt when EBIT declines. Instead, the debt carries an interest coverage ratio covenant, setting a minimum coverage ratio δ of EBIT X_t to coupon C. In other words, leverage ratio fluctuates between refinancing times, and the firm defaults if and when EBIT X_t first falls to the level $H = \delta C$ before the next refinancing.

Denote by X_0 the level of EBIT X_t at the time when the debt was issued, and by ϕ a constant greater than 1. The firm's financing strategy is to refinance the debt if and when EBIT X_t first reaches the level $K = \phi X_0$ before defaulting, at which time the firm repays the outstanding debt with coupon C and issues new debt with coupon ϕC. After refinancing, the minimum coverage ratio is again δ, so that the firm defaults on the new debt if and when EBIT X_t first falls to the level ϕH before reaching the level ϕK, and refinances if and when EBIT first hits the level ϕK before reaching the level ϕH. The refinancing process repeats itself if and when EBIT reaches the levels $\phi^2 K$, $\phi^3 K$, etc., with the firm defaulting if and when EBIT reaches one of the levels $\phi^2 H$, $\phi^3 H$, etc.

Let $H \le X \le K$ and denote by $P_{HK}(X; H, K)$ the price of a double-barrier option that pays \$1 when EBIT X_t, starting from X, first hits the barrier H before hitting the barrier K. Similarly, denote by $Q_{HK}(X; H, K)$ the price of a double-barrier option that pays \$1 when EBIT X_t, stating from X, first hits the barrier K before hitting the barrier H. Then the value VTSX_0 of interest tax shields when EBIT is X_0 satisfies the recursive equation

$$VTS(X_0) = \frac{T_c C}{r_F} [1 - P(X_0; H, K) - Q(X_0; H, K)] + \phi VTS(X_0) Q(X_0; H, K)$$
(71.27)

Solving Equation 71.27 for VTSX_0, we get

$$VTS(X_0) = \frac{T_c C}{T_c C} r_F \frac{1 - P(X_0; H, K) - Q(X_0; H, K)}{1 - \phi Q(X_0; H, K)}$$
(71.28)

Equipped with the value of VTSX_0, we can calculate the value of interest tax shields for any level X of EBIT X_t such that $H \le X \le K$ by writing

$$VTS(X) = \frac{T_c C}{r_F} [1 - P(X; H, K) - Q(X; H, K)] + \phi VTS(X_0) Q(X; H, K)$$
(71.29)

Combining Equations 71.28 and 71.29 and using shorthand notation for PX; H, K and QX; H, K, we get a valuation formula for any $H \le X \le K$

$$VTS(X) = \frac{T_c C}{r_F} \left[1 - P - Q + (1 - P_0 - Q_0) \frac{\phi Q}{1 - \phi Q_0} \right]$$
(71.30)

We can think of the term $1 - P - Q + (1 - P_0 - Q_0) \frac{\phi Q}{1 - \phi Q_0}$ in Equation 71.30 as a risk adjustment factor for either the amount of interest tax shield $T_c C$ or the corporate tax shield T_c.

The valuation and properties of barrier options have been studied by Rubinstein and Reiner [1991] and Derman and Kani [1996, 1997]. Theoretical prices of the double-barrier options used here have also been derived by Gerber and Shiu [1994] using martingale methods, and by Goldstein et al. [2001] using partial differential equations. For any $H \le X \le K$ we have

$$P(X; H, K) = \frac{\left(\frac{H}{K}\right)^{b_m} \left(\frac{H}{X}\right)^{b_p} - \left(\frac{H}{K}\right)^{b_p} \left(\frac{H}{X}\right)^{b_m}}{\left(\frac{H}{K}\right)^{b_m} - \left(\frac{H}{K}\right)^{b_p}}$$

$$Q(X; H, K) = \frac{\left(\frac{H}{X}\right)^{b_m} - \left(\frac{H}{X}\right)^{b_p}}{\left(\frac{H}{K}\right)^{b_m} - \left(\frac{H}{K}\right)^{b_p}}$$
(71.31)

where

$$a = \frac{g - (r_A - r_F)}{\sigma^2} - \frac{1}{2}$$

$$\text{and} \quad b_m = a - \sqrt{a^2 + \frac{2 r_F}{\sigma^2}}$$
(71.32)

71.5.1 Example

The firm's EBIT is $X = 100$, debt was originally issued at EBIT $X_0 = 60$, with coupon $C = 20$, and minimum interest coverage ratio $\delta = 1.5$. First refinancing will occur at $K = 120$ and, thereafter, at multiples $\phi = 2$ of the previous level of refinancing. Mean growth rate of EBIT is $g = 7\%$, volatility of EBIT is $\sigma = 20\%$, risk-free interest rate is $r_F = 6\%$, required asset return is $r_A = 12\%$, and corporate tax rate is $T_c = 25\%$.

Then the default barrier is $H = 30$, the refinancing barrier is $K = 120$, and, from Equation 71.32, the risk exponents are $b_p = 1.5000$ and $b_m = -2.0000$. Therefore, from Equation 71.31, the prices of the double-barrier options at the time of debt issue were PX_0; H, $K = 0.3248$ and QX_0; H, $K = 0.2297$. From Equation 71.28, we get the value of

Table 71.3 Value of interest tax shields for a range of EBIT and business risk

X	σ				
	0.10	0.15	0.20	0.25	0.30
80	110. 52	105. 73	92. 12	77. 20	63. 91
100	139. 02	131. 63	114. 06	95. 31	78. 77
120	180. 41	162. 70	137. 33	113. 11	92. 68
140	237. 84	200. 41	163. 03	131. 50	106. 40
160	314. 13	245. 59	191. 66	150. 90	120. 30

$$D(X_0) = \frac{C}{r_F}[1 - P(X_0;H,K) - Q(X_0;H,K)]$$
$$+ \min[(1-\theta)W(H),F]P(X_0;H,K) + FQ(X_0;H,K) \tag{71.33}$$

Assume that debt was originally issued at par, then $DX_0 = F$. Solving Equation 71.33 and $DX_0 = F$ for face value F, we get $F = 235.30$. Using this face value, it is easy to calculate the cost of debt at issue and recovery rate at default as

Table 71.4 Comparison of valuations of interest tax shields

1	2	3	4	5	6
Modigliani-Miller	Miles-Ezzell	Modified Miles-Ezzell	Modigliani-Miller with Growth	Fernandez	Couch-Dothan-Wu
62. 50	103. 70	100. 00	500. 00	150. 00	82. 73

interest tax shields at the time of debt issue as $VTSX_0 = 68.67$.

In contrast to the models in Sections 71.3 and 71.4, the value of interest tax shields in this framework depends on both business risk and the level of EBIT. Table 71.3 presents sensitivity analysis of this relationship, changing one parameter at a time while keeping the other parameters constant. Thus, the values in Table 71.3 assume that the firm may change business risk σ without changing systematic risk as reflected in the required asset return r_A. If both business risk and systematic risk change, we have to use Equation 71.30 to compute the new value of interest tax shields. It is also important to keep in mind that the tax benefits in Table 71.3 are gross of deadweight default cost, and that subtracting the value of deadweight deafault cost reduces those tax benefits.

For a comparison, Examples 71.3.2, 71.3.4, 71.4.1, and 71.4.2 use the data $D_t = 250$, $r_D = 8\%$, $r_A = 12\%$, $g = 7\%$, $C_t = 20$, and $T_C = 25\%$, and produce the valuations presented in columns 1–5 of Table 71.4. The calculation for column 6 is shown below.

To calculate the value in column 6, we need to compute EBIT X for which the market value of debt is $D_t = 250$ that was used in all the previous examples. Denote by F the face value of debt, by θ the deadweight default cost as percentage of enterprise value at default, and set σ = 25% and θ = 30%. The choice of θ is consistent with empirical findings for liquidation cost reported by Gilson [1997] to average 36.5%, and by Alderson and Betker [1995] to average 45.3%. Hackbarth et al. [2006] use 40.0%, computed as an approximate average of those two numbers. Our choice of a smaller value θ = 30% reflects the fact that it represents a default cost rather than liquidation cost. Enterprise value at default is calculated as $WH = 225.00$.

Similar to the analysis of Fischer et al. [1989] and Goldstein et al. [2001] we get a valuation formula for debt

percentage of face value

$$\text{Cost of debt at issue } r_{0,D} = \frac{C}{F} = 8.50\%$$

$$\text{Recovery rate at default} = \frac{(1-\theta)W(H)}{F} = 66.94\% \tag{71.34}$$

It is interesting to note that this recovery rate at default is within one standard deviation of the mean recovery rate for U.S. nonfinancial corporations over the past 20 years, reported by Covitz and Han [2004] as $40 \pm 28\%$. Given F, we can rewrite Equation 71.33 with X instead of X_0, set $DX = D_t$, and solve the resulting equation for X, yielding $X = 85.97$. As constructed, when $X = 85.97$, the market value of of debt is $DX = 250.00$, and cost of debt is $r_{D,t} = \frac{C}{D_t} = 8.00\%$. Then, with σ = 25% and $X = 85.97$, the value of interest tax shields, computed from Equation 71.30, is $VTS_t = 82.73$. This value is greater than the Modigliani-Miller value because of positive growth, and less than the Miles-Ezzell (and modifed Miles-Ezzell) value because of the asymmetric and infrequent rebalancing of debt, and the explicit modeling of the loss of interest tax shields if and when the firm defaults.

Conclusion

Financing effects are an important part of valuation, and the adjusted present value method (APV) helps make those effects more visible. To perform APV valuation, we need to assess the value of interest tax shields.

The finance literature offers several popular methods of valuation of interest tax shields. The methods are based on different sets of assumptions and/or heuristics, often limiting the firm's financing strategies, and produce somewhat different results. In this chapter, I reviewed

and illustrated several such methods, and commented on their validity and applicability.

In addition, researchers are developing new, dynamic models of valuation of interest tax shields that allow more flexible financing strategies. The chapter reported on such new work, and presented a summary that compares the valuation outcomes of the various methods.

Abstract

This paper aims to study the current rules regarding preparation of cash flow statements, as proscribed by Financial Accounting Standards Board (FASB) and pinpoint the problems with the current rules.

The problems with the existing rules under SFAS-95 can be classified into four broad categories: problems arising from the current three-way classification of cash flows, problems due to the method chosen for preparation of cash flow statements, problems due to the ambiguities in the current rules and problems due to the loopholes in the rules that allow manipulation of cash flows. Several examples of each inconsistency and ambiguity are provided using Johnson & Johnson (JNJ) cash flow statements for 2011.

We use an illustrative method to highlight the need for changes in the existing rules regarding cash flow statements. By showing that under the current rules, several cash flows get misclassified, leading to unclear and confusing financial reports, we hope to make the readers of the financial statements aware that the amounts reported as cash flow from operating, investing, and financing activities do not reflect all of the cash consequences of these activities and that the reported amounts should not be used in decision models without adjustment. We also hope that the FASB will be persuaded to amend SFAS-95 to eliminate the ambiguities and conform more closely to the finance literature, so that the information in the cash flow statement becomes more useful to report users.

Since a primary objective of financial reporting is to provide information to help accounting users assess the amount and timing of future cash flow and earnings, removing some of the ambiguities and other improvements suggested in the paper will not only make these statements more useful in credit and investment decisions, it will also lead to an increased usefulness of financial ratios which currently use information from the cash flow statements, such as operating cash flow, in either the numerator or denominator.

72.1 Introduction

A flood of literature in accounting on earnings management indicates the obsession of auditors, accountants, investors and analysts with reported earnings number.[1] However, a

[1] See Finger (1994).

number of recent corporate scandals are bringing home the realization that corporate management can manipulate earnings in various ways. Furthermore, accrual accounting fails to provide adequate information about the liquidity of the firm and its long-term solvency. As a result, an increasing number of investors and analysts have turned their focus towards the Statement of cash flows (SCF).

The statement of cash flow plays an important role in fundamental securities analysis.[2] It is intended to help predict the firm's ability to sustain (and increase) cash from current operations. As noted in the statement of Financial Accounting standards (SFAS) No. 95, a SCF "provides useful information about an entity's activities in generating cash through operations to repay debt, distribute dividends, or reinvest to maintain or expand operating capacity". For example, comparing operating cash flow with net income is necessary to assess the reasons for the differences between net income and cash flows. Similarly, Investing and financial cash flows can reveal how a firm's asset mix and financing mix is changing. Analysis of cash flow statement can also provide useful insights into the company's ability to generate future cash flows, pay dividends and meet other future obligations, reveal trends in cash flow components and cash consequences of investing and financing decisions.[3] The statement can also convey many crucial management decisions regarding financial policy (leverage), dividend policy and investment policies for future growth. Moreover, Many Cash flow ratios, valuable in evaluating a firm's short term as well as long-term liquidity, use cash flow from operations and other information in the SCF.[4] Thus, it is necessary that this statement is as transparent and user friendly as possible.

Given the vital importance of cash flow statements, it is surprising that while a plethora of authoritative guidance surrounds the calculation and presentation of earnings, existing FASB rules say so little on this important piece of information. Only SFAS 95 specifically addresses the cash flow statement, and only 15 paragraphs within SFAS 95 discuss the appropriate categorization of cash expenditures within the cash flow statement. Moreover, the current format of cash flow statement does not provide either the cash flow from assets or the total of cash flow to creditors and stockholders, a number most useful to analysts, investors and finance experts.[5]

This paper aims to study the current rules regarding preparation of cash flow statements, as proscribed by Financial Accounting Standards Board (FASB) and pinpoint the

problems with the current rules. Some of these problems are due to the arbitrariness of the classifications by FASB. Some others are due to the method chosen for preparation of cash flow statements while others stem from loopholes in the rules that allow manipulation of cash flows in much the same way as earnings manipulation.

The paper hopes to highlight that the three-way classification under SFAS-95 results in reporting similar cash flows differently and different cash flows similarly, just the opposite of the desired characteristic of financial reporting. Several examples of each inconsistency and ambiguity are provided using Johnson & Johnson (JNJ) cash flow statements for 2011.

By highlighting these inconsistencies and ambiguities of SFAS-95, we hope that users of the statements will be more aware that the amounts reported as cash flow from operating, investing, and financing activities do not reflect all of the cash consequences of these activities and that the reported amounts should be used cautiously in decision models. It is also hoped that the FASB will be persuaded to amend SFAS-95 to eliminate the ambiguities and more closely conform the classification rules to the finance literature, so that the information in the cash flow statement more closely conforms to the decision models and therefore becomes more useful to report users.

72.2 FASB Rules for Cash Flow Statements

FASB Statement No. 95 (SFAS-95)[6] requires firms to provide a cash flow statement for each period for which results of operations are provided. The cash flow statement explains the change in cash and cash equivalents, and classifies cash receipts and cash payments as resulting from operating, investing, or financing activities. In addition, firms with significant foreign operations are required to report a fourth category called the effect of foreign exchange rate changes on cash, which accumulates the effects of changes in exchange rates on foreign currency transactions.

72.2.1 Operating Activities

In SFAS-95, the FASB defines operating activities as a residual category to include all transactions and events other than investing and financing activities. It notes that operating activities generally relate to producing and delivering goods and providing services, and that the cash flows from operating activities are generally the cash effects of

---

[5] See Bowen et al(1986) and Dechow et al (1994,1998).

[6] See FASB(1995).

transactions and other events that enter into the determination of net income.

Specifically, operating cash inflows include customer collections from the sales of goods and services, interest and dividend collections on debt and equity securities of other entities, and all other receipts not defined as investing or financing inflows, such as supplier refunds, collections on lawsuits, and most insurance proceeds. Operating cash outflows include interest payments (unless capitalized), payments for inventories, payments to employees, payments to suppliers of other goods and services, payments to governments for taxes, duties, fines, and other fees, and all other payments not defined as investing or financing outflows, such as customer refunds, payments under lawsuits, and charitable contributions.

72.2.2 Investing Activities

SFAS-95 defines investing activities to include making and collecting loans and acquiring and disposing of debt or equity instruments and plant assets.

Thus, Investing cash inflows include receipts from collecting loans, receipts from sales of debt or equity securities of other entities, and receipts from sales of plant assets. Note that under SFAS-95, interest and dividend collections are classified as operating inflows, not investing inflows. Investing cash outflows include payments to make or acquire loans, payments to acquire debt or equity securities of other entities, and payments to acquire plant assets.

72.2.3 Financing Activities

SFAS-95 defines financing activities to include obtaining resources from owners and providing them with a return on their investment; borrowing money and repaying amounts borrowed, or otherwise settling the obligation; and obtaining and repaying other resources obtained from creditors on long-term credit.

Under SFAS-95, financing cash inflows include proceeds from issuing debt or equity securities and from other short- or long-term borrowings. Financing cash outflows include dividend payments, outlays to reacquire or retire equity securities, and repayments of amounts borrowed.

Note that under SFAS-95, interest payments are classified as operating outflows, not financing outflows. So while interest and dividends received is an operating cash inflow, interest payments and dividends paid are financing cash outflow.

The rationale offered in SFAS-95 for the three-way distinction among operating, investing, and financing cash flows is that investors and creditors consider the relationships among certain cash flows to be important to their analysis of financial performance, and that classifying cash flows as operating,

investing, and financing facilitates the evaluation of significant relationships within and among these basic activities. This classification, the FASB notes "links cash flows that are often perceived to be related, such as cash proceeds from borrowing transactions and cash repayments of borrowings . . . [and results in a cash flow]. . . statement which reflects the cash flow impact of each of the major activities of the enterprise." In general, operating activities involve income statement items, investing activities involve cash flows resulting from changes in investment and long term assets and financing activities involve cash flow resulting from changes in long term liability and stockholders' equity.

The finance literature notes that investing and financing decisions are interrelated and that both are related to operating decisions. Nevertheless, the finance literature posits that, for many purposes, it is useful to distinguish between investing decisions and financing decisions and to separate investing and financing decisions from operating decisions.

Comparing the three-way classification of SFAS-95 to the finance literature emanates from the decision usefulness orientation of financial reporting. Because a primary objective of financial reporting is to provide information that is useful in credit and investment decisions, cash flow statements should provide information needed for credit and investment decision models. Many of these decision models are specified in the finance literature and use financial ratios. For example, analysts, researchers and textbooks calculate certain financial ratios that use operating cash flow in either the numerator or denominator. The usefulness of these ratios as well as cash flow information generally should be enhanced by classifying cash flows in the cash flow statement as they are classified in the finance literature.

Although the three-way classification of SFAS-95 is loosely based on the finance literature, certain modifications result in inconsistent or ambiguous classifications of certain cash flows. Accordingly, reported cash flow from operating activities under SFAS-95 frequently includes cash flows from investing and financing activities. Similarly, reported cash flows from investing activities and financing activities frequently exclude certain cash flows properly attributable to them.

The aim of this paper is to emphasize that the operating cash flows should reflect the cash effects of items included in calculating operating income for the same period. Thus, the operating section of the SCF should provide a cash basis measure of the company's performance in much the same way that income statement provides an accrual basis measure.

72.3 Statement of Cash Flows: Methods

The general format of the statement lists the three activities described above. The operating section always appears first, followed by the investing activities and then the financing

activities. The net increase or decrease in cash reported should reconcile the beginning and ending cash balances in the comparative balance sheets.

There is some flexibility in summarizing the sources and uses of funds in a cash flow statement. Although the type of information presented is similar, the exact order and level of aggregation may differ from one preparer to the next. As we will see in the cash flow statement of J& J, a large amount of aggregation is used under "Other Assets" and "other Liabilities" categories in the cash flow statement, making it very hard to understand and analyze these numbers.

Both FASB and IASB standards allow either the direct or the indirect method to determine cash flows, but both encourage DM presentation.[7] However, a large majority of firms currently disclose cash flows using the indirect method. Since the firms are allowed to choose either method for a cash flow statement, a deeper look into the properties of firms that self select themselves into Indirect Method will help standard setters in understanding the costs and benefits firms face when making a choice.

The indirect method, also called the reconciliation method, starts with net income and adjusts it for items that affected net income but did not affect cash. To calculate net cash flow from operating activities, the companies add back all non-cash charges to net income and deduct all non-cash credits.

For consistency and comparability, most companies prefer to use indirect method for cash flow statements, although FASB encourages the use of the direct method.

The direct method, also called the income statement method, reports net cash flow from operating activities as the difference between cash receipts and cash payments from operations. In other words, the direct method simply deducts operating cash payments from operating cash receipts.[8] Cash collections typically include cash collected from customers, from interest and dividends or any other sources. Cash payments include cash paid to suppliers for goods, employees for services, to creditors for interest and to government for taxes.

Since the reporting of investing and financing activities is identical under the two methods, we will focus more on operating activities, since the reporting of cash from operations is quite different under the two methods.

---

[7] "Is the direct method for the statement of cash flow preferable to the indirect method, and if so why?" Joint research initiative by FASB and IASB, 2005 .

[8] A CFA institute monograph, 2005 on financial reporting lists direct method as one of the 12 significant reforms needed to improve financial reporting.

Table 72.1 Balance sheet (J&J)

	2011	2010	Change
Cash/equivalents	19,355,000.00	15,810,000.00	**3,545,000.00**

Net earnings	**$ 13,334**

72.3.1 Johnson and Johnson Company: An Example

To facilitate discussion of our objections to the current format of the cash flow statement, we use the example of Johnson and Johnson (J&J) for the most recent year.

It is important to note that the preparation of the cash flows statement is different from the other three basic financial statements – It is not prepared from the adjusted trial balance since the statement requires information concerning changes in account balances over a period of time. The information to prepare this statement comes from comparative balance sheets, current income statement (Since the net income must be adjusted for the effects of accruals to determine cash flows) and selected transaction data to determine how the company used cash during the period.

Tables 72.1 and 72.2 show comparative balance sheets and the income statement for J&J:

A review of the income statement reveals information that would be used in preparing the SCF. There are two important facts to be noted about the income statement: One is that the company does not report any depreciation on the statement and second that interest revenue is included in operating income. In most cases, Companies place interest received in the investing section but interest paid is shown in the operating section. Similarly, most firms place depreciation and gain or loss from sale of assets in the operating section but cash paid for operating assets is shown in the investing section. As shown below in the SCF, J&J shows both interest received and interest paid as operating activities and shows all asset related transactions, including depreciation, in the investing section.

Table 72.3 Indirect method Johnson & Johnson (J&J) company

Statement of cash flow for the year ended December 31, 2011	
Net income/starting line	**13,334,000.00**
Depreciation	2,939,000.00

Cash from financing activities	**−4,980,000.00**
Foreign exchange effects	−6,000.00
Net change in cash	**3,545,000.00**
Net cash – beginning balance	15,810,000.00
Net cash – ending balance	19,355,000.00
Cash interest paid	491,000.00
Cash taxes paid	2,442,000.00

Table 72.3 shows the statement of cash flows for J&J as submitted to the SEC. Note that like most other submitted statement,[9] J&J also uses the **indirect method**.

---

[9] Accounting Trends and Techniques, 2010, reports that out of its 500 surveyed companies, 495(99 %) used the indirect method.

72.3.1.1 Cash Flow from Operating Activities

In the above statement, the company started with the net income, as reported in the income statement, and adjusted it for all:

1. Non cash revenues and expenses (For example, depreciation expense)
2. Increases (decreases) in the balances of all operating assets are subtracted (added): For example, when accounts receivable increase during the year, it implies that cash receipts were lower than revenues. J&J's accounts receivable increased by $207,000 during the year. This amount will be deducted from the net income to arrive at the amount of cash from operations. Similarly, increase in inventories, or any other operating asset, represents an operating use of cash, even though it is not an expense. This will also be deducted from net income to arrive at the cash flow from operations.
3. Increases (decreases) in the balances of all operating liability accounts are added (subtracted). For example, when accounts payable increase during the year, it means that company paid less cash than the expenses incurred. J&J's accounts payable increased by $20,000 during the year. This amount will be added back to net income to arrive at the amount of cash from operations. A similar adjustment is made for the increase in deferred taxes or any other expenses payable, which keeps cash in the business.

A correct procedure to arrive at the amount of net cash flow from operations is to measure change in each operating account on balance sheet to determine whether any changes in balance sheet accounts caused an increase or decrease in cash. A few important points should be noted here:

1. Changes in operating accounts shown on J&J's SCF do not equal the balance sheet changes. For example, the SCF shows that accounts receivables increased by $207,000. However, the balance sheet reports an increase of only $135,000. Similarly, accounts payable increase by $20,000 as per the SCF but the balance sheet shows an increase of $82,000 in accounts payable. It is not clear what accounts for these and other discrepancies in operating assets and liabilities. Perhaps the company has made some adjustments and aggregations, but they are not explained.
2. The SCF shows an increase of deferred taxes of $356,000. A careful look at the balance sheet reveals that deferred taxes are reported thrice: In current assets, in long-term assets and also in long-term liabilities. Moreover, the total of the three is not equal to the amount reported in the SCF.
3. J&J reports an increase in almost all of its long-term assets in the balance sheet, (Land, building, machinery and equipment, construction and goodwill all went up significantly) but the SCF provides only a single number

of additions to property, plant and equipment of $2,384,000, which does not add up to all the increases in asset. Moreover, the SCF reports proceeds from sale of assets in the investing section, but which assets were sold and whether they were sold at a gain or a loss is not revealed. The company also reports significant transactions in investments and in short term debt instruments in the SCF but balance sheet does not even have a category named investments in its asset section. Moreover, the short-term debt does not match the short-term loans payable in the balance sheet. Why is this information not deemed important and why the cash paid for operating assets is not shown in the operating section are major concerns that FASB should address.

72.3.1.2 Cash Flow from Investing Activities

Capital expenditures for long-term assets such as plant, property and equipment, land and Buildings are the primary component of investing cash flow. Capital expenditures may be reported net or gross of proceeds from the sale of these assets. However, trends in gross capital expenditures contain useful insight into management plans. The J&J cash flow statement reports only a net figure for all plant property and equipment, without providing details about changes in their composition.

Other components of cash flow from investing activities include consequences of acquisitions, investments in affiliates and joint ventures. However, segregating operating assets and liabilities acquired in acquisitions may provide useful information about payments made in cash. The J&J cash flow statement reports a capital expenditure of $ 2,384,000 for purchase of various fixed assets. Moreover, they report a cash outflow of $1,269,000 for acquisition of business and another cash outflow of $ 5,470,000 as "Other cash outflow". It is clear that the company engaged in significant acquisition activity during the year. Since most of the company's long term assets went up during the year, it is impossible to figure out how much of the increase in assets is due to purchase of new assets and how much is due to acquisition of another business and its assets and liabilities. This is probably the reason why the changes in balance sheet accounts do not correspond to changes in the cash flow statement.

72.3.1.3 Cash Flow from Financing Activities

Cash inflows from financing activities include additional borrowing and equity financing and cash outflows include repayment of debt, dividend payments and equity repurchase or retirement. The calculation of equity financing cash flows requires separation of net income, dividend declared and changes in valuation accounts included in equity. The J&J cash flow statement reports a significant cash payment for dividends and repurchase of its common stock. The debt

Table 72.4 Direct method: (J&J)

Item	Income statement	Adjustment	Cash
Cash collected from customers			
Net sales	61,587.0		
Increase in accounts receivables		−207.0	**61,380.0**
Cash received from other sources	768.0		768.0

Depreciation		−1,493.8	
Total payments to employees			−17,254.2
For R&D	6,844.0		
Net cash paid for "other assets"		501.0	
Total cash payments for R&D			−7,345.0
For interest	528.0		
Interest payable		−37.0	
Total cash payments for interest			−491.0
For income taxes	3,613.0		
Deferred taxes		−356.0	
Total cash payments for taxes			−3,257.0
Total cash payments	**49,201.0**		**−45,870.0**
Net cash provided by operating activities	**13,261.0**		**16,385.0**

undertaken also increased in both short term and long term categories.

Once the cash flow from operating, investing and financing operations is calculated, the last step is to summarize the net cash flow, which, by definition, must be equal to the change in cash. As indicated at the bottom of the SCF, net increase in cash of $3,545,000 is the same as shown in the balance sheet.

Academics and experts in finance argue that Cash flow statements prepared using the indirect method suffer from a serious drawback: Since this method reports only the net cash flow from operations, it does not allow a comparison and analysis of operating cash inflows and outflows by function with the revenues and expense activities that generated them.

Hence it provides little new information about the specific components of a firm's cash generating ability.

As a majority of firms provide only the indirect method statement, it is often necessary to convert an indirect one into a direct one. The main advantage of **the direct method** is that it shows operating cash collections and payments and is therefore more consistent with the basic purpose of the statement – to provide information about company's cash receipts and payments. Advocates of the direct method argue that information about the specific sources of operating cash receipts and the purposes for which operating cash payments were made is more useful to users than the net cash flow from operating activities.

Under the direct method, net cash from operations is computed by adjusting each item in the income statement from the accrual basis to the cash basis. An efficient way to apply the direct method is to adjust each revenue and expense reported in the income statement in the order in which it is listed. Table 72.4 shows a direct method statement of cash flows for J&J Company. We use the data from Table 72.1 (Comparative Balance Sheets) and Table 72.2 (Income statement) to calculate the following:

Cash Collections: The income statement reported revenues from customers of $61,587,000. But in order to determine how much of it was collected in cash, we have to look at the change in accounts receivable during the year. Since it increased by $207,000, this much revenue did not translate into cash. Thus, it will be deducted from sales revenue to arrive at the amount of cash collected from customers. Net income also reports interest collection of $ 107,000. Finally there is "Other net income" of $768,000, which could be gain from sale or purchase of business or other assets.

Cash payments: J&J income statement reported cost of goods sold of $18,792,000. To determine cash payments to suppliers, we deduct increase in accounts payable of $20,000, since the company paid less cash than the expenses incurred. Similarly we deduct a portion of the total depreciation expense from cash payment to suppliers, since it is a non-cash charge. Since the indirect method cash flow statement reported a total depreciation and amortization expense of $2,939,000, it has to be added back to the expenses to arrive at the total cash payments made during the period. We pro-rated the depreciation amount between suppliers and employees, in the absence of any further information. However, it does not influence the net cash provided by operations. Finally, an increase in inventories of $196,000 implied that purchases exceeded cost of goods sold. As a result, it will be added to cost of goods sold to arrive at cash purchases.

The company reported operating expenses of $19,424,000 in the income statement. To determine the cash paid for operating expenses, we must adjust this amount

for any changes in prepaid expenses and accrued expenses payable. A decrease in prepaid expenses of $224,000 implies that cash paid for operating expenses was lower than operating expenses reported in income statement. Hence, it should be deducted from operating expenses. However, the indirect method statement combines this adjustment with a pool of others and reports an increase in "Other non cash items" of $626,000. It is virtually impossible to determine what is hiding inside that number.

The R&D expense of $6,844,000 is adjusted for $501,000 to reflect a net increase in assets that were paid in cash but were not expensed. The SCF prepared by the indirect method shows an increase in "Other Assets" of $574,000. The company's footnote to income statement shows an interest capitalized of $73,000. Since capitalized interest is a source of cash, we subtracted this amount before taking the net amount ($574,000–$73,000 = $501,000) as an increase in cash outlay on some long-term assets.

The income statement reported an interest expense of $528,000, but the cash expense on interest was only $491,000, as reported at the bottom of the indirect method statement. Hence, the difference must be an increase in accrued interest payable of $37,000, which will be deducted from operating interest expense to arrive at the cash payments for interest.

Finally, the income-tax expense of $3,613,0,000 needs adjustment to arrive at the amount of cash taxes paid. The indirect method statement reports that the deferred taxes increase by 356,000, meaning that the company did not pay this amount in cash. If we subtract this from income tax expense, we arrive at $3,257,000 as cash payment for taxes. However, at the bottom of the indirect method statement provided by the company, we are told that the company paid only $2,442,000 for taxes, implying that an additional $815,000 has been added to cash by non-payment of some taxes. It is hard to deduce the company's intention behind this massive aggregation. Sometimes, a careful reading of footnote data may reveal additional information on aggregated accounts.

It should be noted that the net cash of 16,385,000 provided by operating activities under the direct method is the same as the number in the indirect method statement.

72.4 Problems with Cash Flow Statements

An operating cash flow Statement has long been considered a reliable barometer of a firm's financial health and less susceptible to creative accounting than its cousins the income statement and the balance sheet. However, recent corporate scandals as well as some research suggest that cash flow statements may also be susceptible to manipulation by corporate managers.[10]

The events surrounding the accounting debacles of Adelphia,[11] Dynegy, Qwest, Tyco,[12] WorldCom, and others demand a new look at this key financial statement, particularly because these cases reflect problems in reporting of cash flows by these corporations. Certain accounting shenanigans have been used to artificially boost reported cash flow or mask declines in operating cash flow.[13]

As further evidence of potential manipulation, the Securities and Exchange Commission recently forced seven well-known companies to amend their financial statements. Harley-Davidson, Caterpillar, and General Motors were among the companies affected by the ruling. Their 2002 and 2003 financial statements classified money owed to them by dealerships as an outstanding investment, meaning that the operating cash flows they reported were artificially high. Harley's 2003 cash flow was 29 % lower after the restating; Caterpillar's tumbled by a staggering 372 %. At GM, these reclassifications reduced its operating cash flow from $7.6 billion to $3 billion.[14]

Research out of Georgia Tech's business school has also found that a number of prominent companies routinely "miscategorize money due from vendors, such as members of their distribution network. Typically, firms record the IOUs as part of their cash flow from investments rather than as reductions to their operating cash flow."[15] Other practitioners and researchers have also pointed out to the existing flaws in rules regarding cash flow statements.[16]

---

[10] See for example, Sender (2002).

[11] See Solomon, Deborah. (2002).

[12] See Maremont (2002).

[13] "For example, after WorldCom's reverse- engineering subterfuge, many have learned to look for excessive capitalization of cash expenditures. Others now scrutinize the cash flow statements for non-recurring sources of cash, such as receipt of an income tax refund and securitization of payables." Mark A. Siegel, "Accounting shenanigans on the cash flow statement" March 2006.

[14] Judith Burns," SEC tells Automakers to re-tool cash flow accounting", Wall street Journal Online (February 28, 2005).

[15] "SEC acts to curb cash flow shenanigans" by Darren Dahl, Inc.com, June9, 2005.

[16] See for example, Cash flow myths. By: Rosen, Al, Canadian Business, 00083100, 3/12/2007, Vol. 80, Issue 6, "We tell our institutional money-managing clients that all cash flow mistakes result from the arbitrary timing or classification of management actions or inactions. The cash flow statement represents cash amounts. But, they are unevenly categorized, and worst of all, smoothed and shifted from period to period. ... Investors tend to forget that accounting cash flows are not "real." Actual cash flows into a company are first recorded using an accrual (non-cash) income basis, and then translated back into a quasi-cash basis on the cash flow statement. This back-and-forth dance creates what I like to call leakage. Leakage can be caused by pension plans, income taxes, stock options, corporate acquisitions, minority interests, asset securitizations and a host of other factors".

The accounting problems brought to light raise important questions about current accounting standards for the statement of cash flows and how they are being applied: Is the statement as useful to investors and creditors as it should be?[17] Can it and should it be improved? Would improvements in the statement increase investors' and creditors' confidence in financial accounting and reporting? We will classify our criticism of existing rules under three categories: Problems due to the arbitrariness of classifications of cash flows of different types, problems due to the method chosen for the preparation of the SCF and problems due to a possible manipulation of several items reported in the SCF.

72.4.1 Arbitrariness of Classifications

Most classification systems are somewhat arbitrary. Classification involves weighing the relative significance of similarities and differences. Under SFAS-95, the unavoidable arbitrariness of the three-way classification sometimes results in classifying similar cash flows differently and different cash flows similarly. Additionally, although the three-way classification of cash flows under SFAS-95 links certain related cash flows, it does not link other cash flows that are either functionally or legally related.

72.4.1.1 Operating Versus Investing Activities

Under the current rules, FASB classifies the purchases of inventory as operating activities and purchases of plant assets as investing activities largely because "payments to suppliers for inventories are regarded normally as part of operating activities and payments for property, plant, and equipment as part of investing activities."

During the past 20 years, many researchers have argued that the purchase and sale of inventories is fundamentally the same as the purchase and sale of plant assets; both are usually considered part of a firm's normal operating activities. The case for treating the purchase and sale of plant assets differently from the purchase and sale of inventories must be based on the grounds that they are of different significance to those interested in the cash inflows and cash outflows of a business enterprise. Although the purchase and sale of plant assets are of special significance because they are of relatively infrequent occurrence, because they are often relatively large in amount, and because management is likely to have more control over their timing than it does over the purchase and sale of inventories, Nonetheless, distinguishing between operating and investing activities is likely to be troublesome.

Thus, to the extent that payments for inventories and plant assets are fundamentally alike, the distinction between operating and investing activities is flawed or unnecessary. This notwithstanding, a consensus has developed that payments for inventories should be classified as operating outflows whereas payments for plant assets should be classified as investing outflows, consistent with the finance literature.

72.4.1.2 Operating Versus Financing Activities

Although the accounting profession talks about the importance of comparability of financial information, the fact that interest paid is treated as an operating activity while dividends paid is treated as a financing activity makes it difficult, if not impossible, to compare the performance of companies that make different financing choices.

Clearly, interest and dividend collections result from making loans or investments in debt and equity securities and, therefore, relate to investment activities. Similarly, interest payments result from incurring debt and, therefore, relate to financing activities. Indeed, the finance literature emphasizes the similarity of interest and dividend payments – interest is paid for the use of debt capital, whereas dividends are paid for the use of equity capital. It follows, therefore, that interest and dividend receipts are not operating inflows and interest payments are not operating outflows, notwithstanding SFAS-95.

The FASB acknowledges that a reasonable case could be made for classifying interest payments as financing outflows and interest and dividend collections as investing inflows. But the FASB notes that traditionally, interest collections and interest payments have been classified as operating flows. Additionally, it perceives widespread support for what might be referred to as the inclusion concept, whereby "... operating cash flow should, insofar as possible, include items whose effects are included in determining net income to facilitate an understanding of the reasons for the differences between net income and net cash flow from operating activities." Because of this inclusion concept, the FASB concludes that it "... was not convinced that changing the prevalent [prior] practice ... would necessarily result in a more meaningful presentation of cash flows."

It is inconsistent, however, for the FASB to cite the inclusion concept and prior practice to decide that cash flow from operating activities should include interest payments and interest and dividend collections but exclude cash flows relating to gains and losses from plant asset disposals. Like interest payments and interest and dividend collections, gains and losses on plant asset disposals are traditionally included in net income, and the cash flows relating to these gains and losses have been included in operating funds flow under prior practice.

---

[17] See for example, Livnat and Zarowin (1990).

By classifying interest and dividend collections and interest payments as operating cash flows, the FASB has foregone the opportunity to more substantially improve the quality of financial reporting by sharpening the distinction among operating, investing, and financing cash flows. It should reconsider the issue.

A similar ambiguity arises in classifying payments of amounts borrowed. Cash outflows to suppliers and lenders are fundamentally alike, yet the former are classified as operating whereas the latter are classified as financing under SFAS-95. It is generally argued that some activities with a financing dimension, such as inventory purchases on account, should be excluded from financing activities because their spontaneous financing components are incidental to an enterprise's operations and do not affect its capital structure. In its 1980 Discussion Memorandum, the FASB also notes this ambiguity in the three-way classification. Nevertheless, FASB still favors classifying cash outflows to suppliers as operating and cash outflows to lenders as financing.

There are at least two inconsistencies in the reasoning underlying this classification. First, it assumes that inventory purchases on account always involve current liabilities. Second, it assumes that report users are interested principally in the capital structure, which excludes current liabilities. What about those admittedly less common situations where inventory purchases on account involve long-term liabilities? What about those report users interested in the financial structure, which includes all liabilities, not just long-term liabilities?

Because cash outflows to suppliers and lenders are fundamentally alike, the distinction between operating and financing activities based on payee is ambiguous. This ambiguity has been resolved by classifying outflows to suppliers as operating and outflows to lenders as financing, consistent with the finance literature.

Another ambiguity in classification involves "**capital leases.**" It is true that, on day one, a lease is a noncash transaction. However, the payment for the lease principal and interest in later days is undoubtedly a cash flow event in a single transaction. And yet, the payment for the principal is treated as a financing activity, while the payment for the interest is shown as an operating activity. One transaction is broken into two parts; it has lost its wholeness. It would be more informative if both were brought together as one transaction under financing activities.

72.4.1.3 Investing Versus Financing Activities

SFAS-95 classifies cash flows according to the transactions that cause them. Cash inflows are not classified according to uses and, similarly, cash outflows are not classified according to sources. For example, cash receipts from the sale of plant assets are investing inflows even when the proceeds are used to retire debt, and cash receipts from issuing debt are financing inflows even when the proceeds are used to purchase plant assets. Such cash inflows and outflows might be viewed as functionally related, but are not necessarily "linked" and are not reported in the same section of the cash flow statement under SFAS-95.

72.4.2 Direct Versus Indirect Method Controversy

As mentioned before, companies favor the indirect method of preparing SCF, even though FASB recommends use of the direct method. The main advantage of the direct method is that it shows operating cash collections and payments and is therefore more consistent with the basic purpose of the statement – to provide information about company's cash receipts and payments.[18] Indirect method does not report operating cash receipts and payments. Advocates of the direct method argue that information about the specific sources of operating cash receipts and the purposes for which operating cash payments were made is more useful in determining a company's future ability to generate cash flows to meet its obligations, to reinvest in its operations and to pay dividends to its owners.

Most companies argue that their accounting systems do not collect information in a manner that allows them to determine amounts such as cash received from customers or cash paid to suppliers. They prefer to use the indirect method since it is less costly to adjust net income to net cash flow than it is to report operating cash receipts and payments. Companies have lobbied against the direct method, urging FASB to adopt the indirect method.[19]

It is ironical that the statement of cash flows under either method does not meet the needs of the finance community, which is often interested in knowing how much cash was taken out of the business in a given year.[20]

Finance textbooks and academicians argue that a cash flow statement should be able to summarize the cash activities of a firm much the same way as income statement summarizes the accrual activities of a firm.

---

[18] Orpurt and Zang (2009) show that direct method leads to a better forecast of future operating performance and cash flows.

[19] Accounting Trends and Techniques published by the American Institute of Certified Public Accountants (AICPA, 2005) reports that of 600 U.S. public firms surveyed over 2001–2004, only seven or eight firms disclosed DM statements of cash flows each year. Because few firms were expected to use the DM, FASB requires DM disclosing firms to also provide an IM schedule for comparability (SFAS No. 95, paras. 29–30). However, no separate DM schedule is required with IM statements. Miller and Bahnson (2002) argue that dual reporting required with DM disclosure may cause managers to prefer the IM.

[20] See Ross et al. (2010).

Table 72.5 Changes in Cash Flow (J&J)

	2011	2010	Change
Sources of cash			
Increase in liabilities			
Loans and notes payable	7,617,000.00	6,318,000.00	1,299,000.00
Accounts payable	5,623,000.00	5,541,000.00	82,000.00
Accrued rebates	2,512,000.00	2,028,000.00	484,000.00
Income taxes	578,000.00	442,000.00	136,000.00
Deferred taxes	1,447,000.00	1,424,000.00	23,000.00
Long-term debt (Note 7)	9,156,000.00	8,223,000.00	933,000.00
Other liabilities	6,567,000.00	5,947,000.00	620,000.00
Retained earnings	77,773,000.00	70,306,000.00	7,467,000.00
Decrease in assets			
Raw materials	1,073,000.00	1,144,000.00	−71,000.00
Deferred taxes	2,224,000.00	2,793,000.00	−569,000.00
Deferred taxes	5,096,000.00	5,507,000.00	−411,000.00
Prepaid and others	2,273,000.00	2,497,000.00	−224,000.00
Doubtful account	−340,000.00	−333,000.00	−7,000.00
Depreciation	−15,873,000.00	−14,492,000.00	−1,381,000.00
Amortization of intangible	−5,509,000.00	−4,857,000.00	−652,000.00
Total sources			**14,359,000**
Uses of cash			
Increase in assets			
Marketable securities	8,303,000.00	3,615,000.00	4,688,000.00
Accounts receivables – gross	10,114,000.00	9,979,000.00	135,000.00
Goods in process	1,460,000.00	1,395,000.00	65,000.00
Finished goods	2,845,000.00	2,641,000.00	204,000.00
Land improvement	738,000.00	714,000.00	24,000.00
Buildings	9,079,000.00	8,863,000.00	216,000.00
Machinery and equipment	18,032,000.00	17,153,000.00	879,000.00
Construction	2,577,000.00	2,521,000.00	56,000.00
Goodwill	15,294,000.00	14,862,000.00	432,000.00
Intangible – gross	22,225,000.00	21,180,000.00	1,045,000.00
Other assets	3,942,000.00	3,690,000.00	252,000.00
Decrease in liabilities			
Accrued liabilities	4,100,000.00	4,625,000.00	−525,000.00
Accrued compensation and employee relate	2,642,000.00	2,777,000.00	−135,000.00
Employee Obligations	6,087,000.00	6,769,000.00	−682,000.00
Comprehensive Income	−3,531,000.00	−3,058,000.00	−473,000.00
Treasury stock	−20,783,000.00	−19,780,000.00	−1,003,000.00
Total uses			**10,814,000**
Net addition to cash			**3,545,000.00**

Since the balance sheet identity tells us that the value of a firm' assets is equal to the value of its liabilities plus the value of its equity, the cash flow from a firm's assets must be equal to the cash flow to suppliers of capital to the firm. Thus the basic cash flow identity is:

$$\text{Cash flow (CF) from assets} = \text{(CF) to creditors} + \text{(CF) to stockholders.}$$

This identity reflects the fact that a firm generates cash through various activities and that cash is either used to pay creditors or paid out to the owners of the firm.

Cash flow from assets involves three components: operating cash flow, capital spending and change in working capital. Operating cash flow is defined in a slightly different way under finance literature: Expenses associated with firm's financing of its assets, such as interest, are deducted because they are not operating expenses. Depreciation, being a non-cash expense, is added back to earnings.

Capital spending refers to the net spending on fixed assets (purchase of fixed assets minus sale of fixed assets).

Lastly, change in working capital is measured as the net change in current assets relative to current liabilities and represents the amount spent on working capital.

In order to calculate sources and uses of cash in a business, we need to trace the changes in firm's balance sheet to see how the firm obtained and spent its cash during same period. For example in the balance sheet for J&J, net fixed assets increased by 7,766 and its inventory, for all the three categories together, increased by $198. (All figures are in millions.) Where did the cash come to pay for these purchases? To answer this and related questions, we need to identify those changes that brought in cash (sources) and those that used up cash. Logically, if an asset (liability) account increases (decreases) over the period, the firm must have used cash. Similarly, if an asset (liability) account went down (up) over the period, then the firm must have sold some assets (undertaken new liability) – a source of cash. Table 72.1, column 3, shows the change in each item on the balance sheet and the direction of the change. An increase in asset, for example, inventory, is a net use of cash because the firm paid to get additional inventory. An increase in Accounts receivable of $135 is also a use of cash because the company has effectively given a loan receivable by the end of the year. By the same logic, increase in accounts payable of $82 is a source of cash because the company borrowed this amount from its suppliers for a short term. Accrued liabilities, on the other hand, went down by $525, so J&J must have paid off $ 525 worth of short-term debts-A use of cash. Base on this discussion we can summarize the sources and uses of cash from the balance sheet as follows (Table 72.5):

Notice that the net addition to cash is same as the $3,545 change on the balance sheet. This statement, although simple, tells us what happened during the year. The company increased its total liabilities by a lot but also acquired a lot of assets. However, it still does not tell the whole story. For example, it does not explain why the increase in accounts payable figure in the balance sheet does not match with the number reported in the indirect method (Many other numbers like increase in inventory, accounts receivable, deferred taxes and depreciation are also different in the two statements). Second, it would be more enlightening to have more details reported. For example, the increase in retained earnings is net income (a source of funds) less dividend (a use of funds) but we don't see the breakdown. Finally, we see only an increase in net fixed assets. Total or gross spending would be more interesting to know.

72.4.3 Manipulation and Distortion of Cash Flow Statements

Recent focus on SCF has revealed that Companies can either artificially boost reported cash flows or present unsustainable cash flows or mask declines in operating cash flows by using many of the loopholes in the existing rules.

The following examples show how companies can employ certain techniques (many of which are within GAAP) to show improved reported cash flows.

72.4.3.1 Manipulation of Payables
The easiest thing that companies can do to improve reported operating cash flow is to slow down the rate of payments to their vendors. A direct consequence of this policy is to boost the reported growth in cash flows from operations. If analysts or investors expect the current period improvement to continue, they may be mistaken; vendors will eventually put increasing pressure on the company to pay more timely. Therefore, any benefit may be unsustainable or, at minimum, any year-over-year improvement in operating cash flow may be unsustainable.

The extension of payables can be identified by monitoring number of days' sales in payables (DSP).[21] This metric is calculated as the end-of-period accounts-payable balance divided by the cost of goods sold and multiplied by the number of days in the period. As DSP grow, operating cash flows are boosted.

A look at J&J accounts payables reveals that the company has been experiencing huge fluctuations in this figure over

the years: Its accounts payable increase by a modest $20,000 in the current year, although it went down by $507,000 and $272,000 in the previous 2 years. The figures show that while the company received a significant benefit to cash flows from operations in 2009 and 2010, that benefit began to slow in subsequent periods, indicating that J&J will probably be unable to continue to fuel growth in operating cash flow using this method

Another important point to note is that the firm shows an increase of $20,000 in accounts payables in the SCF, the balance sheet shows an increase of $82,000. It is surprising that one of the most popular adjustments to accrued expenses is not shown clearly and accurately.

72.4.3.2 Financing and Securitization of Payables
A more complicated version of stretching out payables is the financing or securitization of payables. This occurs when a company uses a third-party financial institution to pay the vendor in the current period, with the company then paying back the bank in a subsequent period. In recent years, increasing concern on keeping debt off the balance sheet has led companies to sales of receivables, with and without recourse. Economically, these activities still represent a form of financing. The accounting rules, however, allow these transactions to be treated as operating activities instead of financing activities. This makes these transactions doubly attractive to companies: They keep the borrowing off the balance sheet and inflate cash provided by operations. Theoretically, the pledge of accounts receivable is the same as the sale of accounts receivable, but they are treated differently in the cash flow statement. This treatment is inconsistent.

An interesting corollary to the impact on operating cash flow from securitizations is the impact on earnings. Specifically, in many cases companies can report gains when long-term accounts receivable are securitized. This occurs because the book value of the receivables at the time they are securitized does not include all the future interest income that is to be earned. Yet the entity purchasing the receivables will have to pay for that interest. As a result, because the amount received for the receivables is greater than the book value, a gain is generated. The amount of the gain can be affected as well by a variety of management assumptions, such as the expected default rate of the receivables securitized, the expected prepayment rate, and the discount rate used.

GAAP does not prescribe where on the income statement this gain is to be recorded. While one company may report the gain on sale of the receivables within revenues (the most aggressive approach), another might record it as an offset to selling, general, or administrative expenses. Another company might report the gain "below the line" in other non-operating income.

---

[21] For a detailed analysis of problems with payables, see Nurnberg (2006).

72.4.3.3 Deferred Employee Compensation

Another serious distortion involves deferred employee compensation. Many companies pay deferred compensation in the form of stock options that are off the balance sheet when issued. When the company later redeems the options by paying cash, the move is treated as a financing activity – as though it were a capital allocation, when in reality this payment is not any different from wages. As such, it should be treated as an operating activity.

72.4.4 Stock Buybacks

A second issue related to stock options that affects reported cash flows is the buyback of company stock. A large number of companies have, in recent periods, been buying back their own stock on the open market. In a majority of cases, this activity is due to stock-option activity. Specifically, when the price of a company's stock rises, many of those who hold stock options exercise those relatively cheap options. If companies do nothing to offset the larger number of outstanding shares that exist as a result of the growing number of in-the-money options, earnings per share can be negatively affected. Management of such companies, therefore, face a choice: They can allow earnings per share to be diluted by the growing share count or they can buy back company stock to offset that dilution.

From an accounting standpoint, the impact of options on the income statement is usually minimal, as discussed above. On the cash flow statement, the tax benefit of option exercises is a source of operating cash flow, benefiting those companies whose option exercises grow. Cash expended by a company for the buyback of corporate stock, however, is considered a financing activity on the cash flow statement. Consequently, as option exercises grow, so does the boost to operating cash flows for the tax benefit, but the outflows for stock buybacks to offset dilution of earnings are recorded in the financing section of the cash flow statement.

Interestingly, as a company's stock price rises, more options are generally exercised and the company must buy back more stock at the ever-higher market prices. In some cases, the entire amount of cash flow generated by operations in recent periods could be expended to buy back company stock to offset the dilution from in-the-money options. (J&J used $27,970,000 to buy back its own shares. This amount is reported as a financing outflow.) Therefore, when analyzing the true earnings power of a company as measured by cash flows, it is important to consider the cash expended to buy back stock to offset dilution. This cash outflow should be subtracted from the operating cash flow in order to calculate the true free cash flow the company generated in the period in question.

72.4.4.1 Marketable Securities

For many years, the distinction between cash equivalents (investments having no principal risk) and other marketable securities has caused serious confusion for the untrained reader of financial statements. Cash equivalents are treated as part of cash, while marketable securities are shown as investing activities. Where a company's portfolio manager does a lot of trading and switching between these two types of securities, very large numbers will appear in the investing activities section as "purchases of marketable securities" and "sales of marketable securities." It is not uncommon to see financial statements in which these numbers represent the largest cash flows. In J&J's balance sheet, marketable securities represent the largest cash outflow: an increase of $4,688,000. Similarly, the SCF reports "Sale of investments" at $11,101,000, which is classified as cash inflow under investing activity. If an untrained reader is asked what the most significant events for the company were during the year, the answer might be the purchasing and selling of marketable securities. Yet these numbers are irrelevant for understanding the company's performance. They merely clutter up the statement and cause confusion. Because SFAS 102 requires the buying and selling of securities to be treated as operating activities, the situation will be even worse.

72.4.4.2 Dividend from Affiliated Companies

Another problem that causes distortions in operating cash flows stems from the treatment of dividends received as an operating activity rather than as an investing activity. When a company has significant investments in affiliated companies, it has the ability to manipulate its own "cash provided by operations" by increasing the dividends it receives from such companies. Furthermore, dividend income comes from investments. If the former is shown in the section of operating activities, and the latter placed in investing activities, the reader of financial statement will not be able to visualize the whole picture of investment strategy.

72.4.4.3 Income Taxes

Another potentially serious distortion to operating cash flows comes from the rule that requires taxes to be treated as an operating activity, even when the gain being taxed is included in investing activities. For example, consider a company that has low operating profit but has a large gain from the sale of investments. The bulk of the pretax income is from this gain, and therefore the bulk of the income tax expense is related to this gain. On the statement of cash flows, however, the gain is removed from operating activities and included under investing activities instead, as part of the proceeds from the sale of the investments. But the

income tax expense on that gain remains in the operating activities sections, generating substantial negative cash from operations. This clearly is misleading, and violates the matching rules required on the income statement.

Because income tax payments and refunds are operating cash flows under SFAS-95, cash flow from operating activities includes the income tax effects of gains and losses relating to investing or financing activities, such as gains and losses on plant asset disposals and similar items.

Income taxes should be allocated in the cash flow statement in order to more accurately distinguish among cash flows from operating, investing, and financing activities.

Under the current rules of SFAS-95, when the amounts are material, it is recommended that firms disclose the income tax effects of gains and losses relating to investing and financing activities, to alert report users that the reported cash flow from operating activities is contaminated by the tax effects of these gains and losses. The J&J cash flow statement reports income taxes under current assets, current liabilities as well as in long-term assets. Although no detail is provided, it is possible that the figures pertain to income tax effects of gains and losses in purchase of businesses or sale of assets.

72.4.4.4 Sale and Purchase of Assets

A major problem with the investing activities section is that it is based on the rule that only cash amounts may be shown in investing and financing activities. Thus, for example, if one company acquired, another at a cost of $10 billion, but only $1 billion of it was in cash, with the rest paid in the form of debt and equity instruments, the cash flow statement would show only the $1 billion cash amount paid as the **cost of the acquisition.** The other $9 billion would be relegated to a footnote. The untrained reader would get a false picture of the true cost of the acquisition. This is another example showing the deficiency of the current rules in preparing the cash flow statement. The rules ignore the vision of a complete transaction.

Moreover, there are certain inconsistencies in reporting installment purchases and sales of plant assets under SFAS-95. For installment purchases of plant assets, only early payments of principal, such as advance payments and down payments, are investing cash outflows; subsequent installment payments of principal are financing outflows. For installment sales of plant assets, however, all installment receipts of principal are investing inflows – not just the early receipts of principal.

The inconsistency results from classifying all installment receipts of principal on sales of plant assets as investing inflows but only some installment payments of principal on purchases of plant assets as investing outflows. Moreover, because most installment payments of principal on

purchases of plant assets are classified as financing outflows, a comparative cash flow statement for a series of years does not report all the investing and financing activities of a firm.

72.4.4.5 Non-cash Transactions

In the Exposure Draft to SFAS-95, the FASB proposed that the primary purpose of the cash flow statement is to provide information about the cash receipts and cash payments of a firm during a period, and that a secondary purpose is to provide information about the investing and financing activities of the firm during the period. Consistent with these two purposes, the Exposure Draft required disclosure of noncash investing and financing transactions either in the cash flow statement or in a separate schedule. Examples of noncash investing and financing transactions include: converting debt to equity, acquiring assets by assuming directly related liabilities, such as purchasing a building by incurring a mortgage to the seller, obtaining an asset by entering into a capital lease, and exchanging noncash assets or liabilities for other noncash assets or liabilities.

Unlike the Exposure Draft, however, SFAS-95 retains the primary purpose but deletes the secondary purpose of the cash flow statement. The FASB concluded that the effectiveness of the cash flow statement would be enhanced if its purpose was restricted to reporting only cash flows, and therefore prohibits reporting noncash transactions in the cash flow statement. Nevertheless, SFAS-95 requires disclosure of all noncash investing and financing transactions that affect recognized assets or liabilities but that do not result in cash inflows or outflows. The FASB reasons (that although these noncash transactions result in no cash inflows or outflows in the periods in which they occur, they generally have a significant effect on cash flows in subsequent periods. SFAS-95 makes more uniform the reporting of noncash investing and financing transactions by prescribing supplemental disclosure outside the cash flow statement and prohibiting their disclosure in the cash flow statement. Unfortunately, the result of this narrower focus is that a comparative cash flow statement, unlike a comparative statement of changes in financial position, does not report all of a firm's investing and financing transactions.

For example, if a firm acquires equipment under capitalized leases, the inception of the lease is a noncash investing and financing transaction to be disclosed outside the cash flow statement, whereas the subsequent lease payments are allocated between interest and principal and reported in the cash flow statement as operating and financing outflows, respectively. Accordingly, a comparative cash flow statement for a series of years does not report all investing and financing transactions relating to this lease. Neither the original investment outflow nor the original borrowing inflow is reported in the cash flow statement, but the repayment is reported later as a financing outflow.

From a cash flow statement perspective, the firm appears to be paying off a phantom loan, although the loan itself is reported in the balance sheet.

A similar result occurs when a firm acquires real estate by assuming an existing mortgage or by giving a mortgage or installment note to the seller. Only the down payment is reported as an investing outflow; all subsequent principal payments are reported as financing outflows.

Still another example of the incomplete reporting of financing activities in the cash flow statement under SFAS-95 is the conversion or exchange of debt for equity. A comparative cash flow statement reports the original borrowing as a financing inflow, but settlement of the debt by conversion or exchange is not reported as a financing outflow because it does not involve cash.

72.4.4.6 Free Cash Flows

Another important deficiency in the current cash flow statement is the absence of the concept of "free cash flow".

Free cash flow is defined as cash without any restrictions on its use. It is available for any purpose at any time. It is similar to the concept of un-appropriated retained earnings. Since earnings are usually appropriated for dividend payout, plant expansion, contingencies, and other needs, cash available after these appropriations would be more useful for management planning.

Free cash flow has become increasingly important in financial statement analysis, yet the accounting profession has ignored it. The authors suggest that the profession take a serious look at free cash flow, with a view to narrowing and standardizing the conceptual definitions. If the traditional cash flow statement can be extended to include a consistent concept of free cash flow, it would become far more informative and useful.

Conclusion

This paper compares the distinctions in SFAS-95 among operating, investing, and financing activities with similar distinctions in the finance literature. It identifies several inconsistencies and ambiguities in the three-way classification of cash flows under SFAS95, and demonstrates how the effectiveness of the cash flow statement to distinguish among operating, financing, and investing activities is impaired.

More specifically, this paper demonstrates that the three-way classification result in reporting similar cash flows differently and different cash flows similarly, just the opposite of the desired characteristic of financial reporting to report similar things similarly and different things differently. The paper pinpoints that the classification of interest, income taxes, and dividend collections as operating cash flows results in contaminating cash flow from operating activities with the interest and dividend

effects of investing and financing activities as well as with the tax effects of gains and losses relating to investing and financing activities. Finally, this paper highlights that the requirements to report third-party financing transactions and disclose noncash investing and financing transactions are ambiguous.

By highlighting these inconsistencies and ambiguities, it is hoped that readers will be more aware of certain limitations of cash flow statements prepared under SFAS-95. More specifically, it is hoped that readers have been made aware that the amount reported as cash flow from operating activities does not reflect all of the cash flow consequences of operating activities and, similarly, that the amounts reported as cash flow from investing and financing activities do not reflect all of the cash flow consequences of investing and financing activities, respectively. Accordingly, these amounts should not be incorporated into operating, investing and financing decision models without adjustment. We hope that FASB will soon recommend some important changes to make cash flow statements more transparent and useful to the investing community.

Nonlinear Models in Corporate Finance Research: Review, Critique, and Extensions[*]

Sheng-Syan Chen, Kim Wai Ho, Cheng-Few Lee, and Keshab Shrestha

Abstract

Since the work of Morck et al. (Journal of Financial Economics 20: 293–315, 1988), nonlinear model specification has gained more attention in corporate finance research. In this paper, we provide a detailed review of the previous studies that have examined nonlinear relations in corporate finance. We review the theory and evidence in these studies and discuss the advantages and disadvantages of the various methodologies used to detect nonlinearity. We also suggest two possible methodological extensions, which we apply in the empirical analysis of R&D investment and firm value.

Keywords

Nonlinear models • Nonlinearity with interaction effect • Residual analysis

73.1 Introduction

Since the work of Morck et al. (MSV) ([1988](#)), nonlinear specification in regression models has gained more attention in corporate finance research. Morck et al. ([1988](#)) first use a piecewise linear regression model to examine nonlinear relationship between board ownership and firm value. Many researchers have since used the methodology to examine other issues.[1] Wruck ([1989](#)) extends the piecewise regression methodology to examine nonlinear relationship between first differences in variables (between abnormal returns and changes in ownership concentration). Thomas ([1995](#)), Martin ([1996](#)) and others adapt the MSV methodology to logistic regressions.

Other studies such as McConnell and Servaes ([1990](#)), Slovin and Sushka ([1993](#)), and Daines ([2001](#)) use a quadratic functional form to examine nonlinear relationships. Fields and Mais ([1994](#)) regress the slope of a function (the ratio of abnormal return to change in management ownership) against the independent variable (the level of management ownership). Finally, Allen and Cebenoyan ([1991](#)) and Pantzalis et al. ([1998](#)) apply switching regressions to investigate nonlinear relations in corporate finance.

In the MSV piecewise regression model the number and locations of turning points are pre-determined. Generally,

two turning points are assumed in most studies although Morck et al. (1988) have also examined models with more than two turning points. Morck et al. (1988) use the sum of squared errors as a criterion to determine the optimal combination of turning points. In most subsequent ownership studies, researchers use the same turning points as in Morck et al. (1988) (i.e., 5% and 25%) without further model specification tests, even in cases where the variables in question are different from those used in Morck et al. (1988).[2] As Morck et al. (1988) pointed out, the theoretical justification for the turning points is not strong. The ground for using the same 5% and 25% turning points for different variables without specification tests is even weaker.

The MSV piecewise regression model assumes that the turning points are pre-determined and sharp and that the relationship is linear between two adjacent turning points. In contrast, the quadratic and higher order polynomial regression models are smooth functions and allow the turning points to be determined endogenously. In switching regression models, break points are also determined endogenously and different relationships between the switching variables and the dependent variables are allowed across different regimes.

In view of the prevalence of nonlinear relationships reported in corporate finance literature, it is important to study the relative merits of various nonlinear models. This paper provides a detailed review of the methodologies used in extant corporate finance research to detect nonlinearity. We also discuss their advantages and disadvantages. Finally, we provide two possible extensions in methodology and present empirical analysis using these extensions. The following section discusses the theoretical and empirical work reviewed in this article. Section 73.3 describes and compares the existing models. The possible problems associated with each model are also discussed. Section 73.4 proposes extensions in methodology and Section 73.5 presents the empirical analysis using these extensions. Section 73.6 provides some concluding remarks.

73.2 Nonlinear Relationships in Corporate Finance Research

This section reviews existing corporate finance literature in which nonlinear relationships are examined. The list of papers discussed here is not intended to be exhaustive. Our aim is to show that nonlinear relations are common in corporate finance research. For ease of discussion, we classify the studies according to the research areas.

73.2.1 Firm Value (or Firm Performance) and Ownership Structure

Many of the corporate finance studies that report nonlinear models are related to ownership structure research. Existing theories suggest that managerial ownership and other ownership variables may have a positive or negative impact on firm value (or performance). The interaction of these effects may give rise to a nonlinear relationship between ownership variables and other variables such as firm value or firm performance. According to Jensen and Meckling's (1976) alignment-of-interests hypothesis, higher managerial ownership would result in lower agency costs and higher firm value. Leland and Pyle's (1977) signaling model also suggests a positive relation between management ownership and firm value. However, Demsetz (1983) and Fama and Jensen (1983) suggest that when a manager owns a sufficiently large stake, negative entrenchment effects may become significant. Stulz (1988) also suggests that the relation between managerial ownership and firm value is positive up to a certain ownership level and becomes negative as management ownership increases further. He argues that the premium a hostile bidder must pay increases with management ownership, but the probability of a successful takeover decreases as management ownership increases.

Morck et al. (1988) empirically test the relationship between board ownership and firm value, as proxied by Tobin's Q, using a piecewise linear regression model. They find a significantly positive relation between board ownership and Q in the 0–5% board ownership range, a significantly negative relation in the 5–25% range, and a weak relation beyond 25%. The authors argue that the entrenchment effects dominate the alignment-of-interests effects in the 5–25% range. Holderness et al. (1999) obtain similar results for their 1935 sample.[3]

McConnell and Servaes (1990) provide empirical evidence supporting Stulz's (1988) prediction. They find a curvilinear relation between insider ownership and Tobin's Q, with turning point for insider ownership at around 49% in the 1976 sample and 38% in the 1986 sample.[4] When the sum of insider ownership and large blockholding is used as the ownership measure, the turning point is about 43% in the 1976 sample and 40% in the 1986 sample. Anderson and Reeb (2003) report a similar quadratic relation between founding-family ownership and firm performance. The inflection point ranges from 27.6% to 31.0%, depending on the measure of firm performance used. Thus, these studies suggest that the location of the turning point is sensitive to the definitions of the ownership and firm performance variables, the inclusion of other variables in the model, and the period of study.

Anderson and Lee (1997) shows that ownership data provided by different databases can affect the empirical results in prior studies.[5] They examine the MSV piecewise linear model, McConnell and Servaes' (1990) quadratic model, and Bagnani et al. (1994) piecewise linear regression relating management ownership to the firm's unsystematic risk. However, in their analysis, they do not include any control variables.

Nonlinear relation between managerial ownership and firm performance is also observed in international studies. For example, Short and Keasey (1999) report a cubic relation between firm performance and managerial ownership for a sample of UK firms, with the turning points at 15.6% and 41.8% managerial ownership. The study shows that institutional factors can influence the location of the point of managerial entrenchment. For a sample of Korean firms before the economic crisis in 1997, Joh (2003) also finds a nonlinear relation between ownership concentration and firm performance using both the piecewise linear regression model and the cubic polynomial specification.

Studies such as Cho (1998) and Himmelberg et al. (1999) suggest that managerial ownership is endogenously determined. Using a simultaneous equation framework, Cho (1998) shows that managerial ownership, specified in piecewise linear form, has no significant impact on firm value. Using panel data, Himmelberg et al. (1999) also cannot conclude that changes in managerial ownership affect firm performance. They examine both the quadratic and the piecewise linear specifications for the ownership variable. Coles et al. (2012) present an optimal-contracting model to explain the nonlinear relationship between corporate performance and managerial ownership. They regress Tobin's Q on CEO ownership and square of CEO ownership to test the nonlinear relation and show that their relationship is inverted U-shaped. Their conclusion is that the endogeneity problem will not be solved by the methods of proxy variables, fixed effects, and instrumental variables in the contextual relation of ownership and performance.

The studies reviewed so far use cross-sectional analysis to examine the nonlinear relation between firm value and managerial ownership. The impact of managerial ownership on firm value has also been extensively researched in event studies. For example, Slovin and Sushka (1993) examine that the relation between the share price response to the death of an inside blockholder and the deceased's shareholding. By partitioning their sample into five ownership subsamples, they show that the abnormal return is significantly positive when the deceased's shareholding exceeds 10% of the firm's shares, beyond which, the larger the deceased's shareholding the more favorable the stock-market response. The positive effect is of smaller magnitude after 40% ownership is reached. In cross-sectional regressions, they find a significant quadratic relation between the abnormal return and the deceased's shareholding. In the subsequent sections, we will discuss several other studies that make use of the event study methodology to show the impact of ownership structure on firm value.

73.2.2 Equity Issues

Adapting the MSV piecewise linear regression methodology, Wruck (1989) finds that when the level of ownership concentration after a private equity sale is low (<5%) or high ($\geq 25\%$), the relation between abnormal return (change in firm value) and *change* in ownership concentration is positive. In the range of 5–25% ownership concentration, this relation is negative. The author suggests that the results are consistent with those of Morck et al. (1988). In contrast, Hertzel and Smith (1993) do not find similar relationship in their sample of private placements.

Fields and Mais (1994) examine the relation between management ownership and abnormal return at the announcement of a seasoned equity issue. They show that the ratio of abnormal return to change in management ownership is negatively related to the level of management ownership. They argue that since the ratio of abnormal return to change in management ownership measures the slope of the firm value function, their results are consistent with the prediction of Stulz (1988). In contrast, Brous and Kini (1994) find that abnormal returns associated with seasoned equity issues are not significantly related to insider ownership and insider ownership squared.

Slovin et al. (2000) find a significant curvilinear relation between excess returns and ownership concentration for placings in the UK, with a maximum point at about 40% ownership concentration. They argue that placings by firms with concentrated ownership enhance value by increasing ownership dispersion. The study finds that ownership concentration does not affect excess returns at insured rights offerings in the UK.

Mikkelson et al. (1997) examine ownership and operating performance of firms that go public. They find that operating performance both within 1 year of the offering and during the first 10 years of public trading is unrelated to the change in insider ownership surrounding the IPO, the insider ownership following the offering, and the square of the insider ownership following the offering. They explain that despite the declines in insider ownership following an IPO, managerial incentives are not materially affected, given the substantial level of insider holdings immediately after the offering. The authors further suggest that the lack of association between operating performance and insider ownership years after going public may be explained by new pressures on managers of a publicly traded firm.

Aggarwal et al. (2002) suggest that substantial underpricing at IPO generates information momentum,

which shifts the demand curve for the firm's stock outwards. They show that higher ownership by managers is positively correlated with underpricing, underpricing is positively correlated with research coverage, and research coverage is positively correlated with stock returns and insider selling at lockup expiration. Using a quadratic specification for underpricing, they find a concave relation between underpricing and research coverage.

Cook et al. (2006) show that the greater the efforts of promotion by investment bankers prior to IPOs, the larger the underpricing of the issue. The efforts of promotion by investment bankers are positively related to the underpricing because the marketing ability of investment bankers is important to promote an IPO to sentiment investors. Since there may exist a nonlinear relationship between total compensation and the total amount sold, they regress the logarithm of total investment banker compensation and the logarithm of total selling compensation on the logarithm of the amount sold and the square of the logarithm of the amount sold. They find that the coefficient on the square term is significantly negative, indicating that there is a nonlinear relationship between total compensation and the total amount sold and that economies of scale in underwriting exist, consistent with the findings of Altinkilic and Hansen (2000).

Kim et al. (2010) examine whether the relationship between issue size and underwriting spreads is nonlinear and U-shaped. They add a nonlinear size term as size multiplied by the market value of equity, and find that the coefficients on both size and the nonlinear term are significantly positive, consistent with Altinkilic and Hansen (2000). Their results show that underwriting spreads (direct costs) and underpricing (indirect costs) are positively related for both IPOs and SEOs.

73.2.3 Corporate Payout Policy

Rozeff (1982) suggests that cash dividend payment forces the firm to the capital market more frequently, thus reducing agency costs as a result of the increased market scrutiny. He proposes that insider ownership and dividend policy are substitute tools used to reduce agency costs. This implies a negative relation between insider ownership and dividend payout. Schooley and Barney (1994) argue that beyond a point of managerial entrenchment, an increase in managerial ownership increases agency costs, and hence, higher dividend payout may be necessary to increase market scrutiny on the firm. They find a curvilinear relation between dividend yield and CEO stock ownership, with a minimum point at 15% stock ownership. Setia-Atmaja et al. (2009) indicate that family controlled firms have higher dividend payout ratios, higher leverage ratios, and lower independent boards

than non-family firms in Australia. For the nonlinear relationship between family ownership and dividends, debt, and board structure, they add a control variable, the square of family ownership. Their results show that the coefficients on the square of family ownership are significant and exhibit an inverse-U shaped, suggesting nonlinear effects of family ownership on dividends, debt, and board structure.

Lie (2000) suggests that special dividends and self-tender offers can reduce agency problems associated with excess cash, especially in firms with poor investment opportunities. The evidence shows that abnormal returns associated with these events are significantly positively related to the cash level prior to the event (CASH) and the interaction variable between low-Tobin's Q firms and CASH (Low Q x CASH). The study further examines whether the relation between the announcement return and the interaction variable (Low Q x CASH) is stronger for firms with poor control mechanisms, which are proxied by four dummies (insider holdings < 5%, insider holdings > 25%, outsiders on board < 50%, and no outside blockholders). The results show that the three-way interaction terms between Low-Q, CASH, and each of the four dummies are not significant.

Alangar et al. (1999) suggest that the information content of dividend-change announcements, as proxied by the absolute value of the announcement return, is related to the degree of pre-announcement information asymmetry, which is proxied by institutional ownership. They argue that the relation may be nonlinear because beyond some level of institutional ownership, further increases in institutional ownership may not result in additional reduction in information asymmetry. The study finds significantly negative coefficients for the two dummy variables that indicate the intermediate and high institutional ownership groups, the omitted set being the group with the lowest institutional ownership.[6] The evidence suggests a positive relation between the information content of dividend-change announcements and the degree of pre-announcement information asymmetry in the stock.[7]

73.2.4 Corporate Debt

Nonlinear relations are also common in corporate capital structure research. For example, Diamond (1991) predicts a nonmonotonic relation between bond rating and debt maturity. Diamond argues that firms with highest credit ratings issue short-term debt because of lower refinancing risk. Firms with lower credit ratings would prefer longer-term debt to minimize refinancing risk. However, firms with very poor credit ratings are unable to borrow long-term because of adverse selection problems. Barclay and Smith (1995) and Stohs and Mauer (1996) provide empirical support for this prediction, though their model specifications are somewhat different. Barclay and Smith (1995) define two

variables: (1) a bond rating dummy that equals one if the firm has a Standard and Poor's (S&P) bond rating and zero otherwise; and (2) a bond rating variable for rated firms that equals one if the firm's S&P bond rating is AAA, through 27 if the rating is CCC or below. They find that both the bond rating variable and the bond rating dummy are positively related to debt maturity, suggesting that nonrated firms have more short-term debt, and among the rated firms, lower-rated firms issue more long-term debt than do higher-rated firms. Stohs and Mauer (1996) construct a bond rating variable, where AAA = 1, ..., CCC = 7, and unrated firms receive a code of 8. Using a quadratic specification for the bond rating variable as well as dummy variables that split the bond rating range into three parts, they find an inverted U-shaped relation between bond rating and debt maturity.

Bagnani et al. (1994) investigate the relation between the pricing of risky debt and management ownership. They argue that when managerial ownership is low, an increase in managerial ownership increases management's incentives to increase stockholder wealth at the expense of bondholder wealth (e.g., higher risk taking). This is expected to lead to higher risk of outstanding debt and higher bond return premia. At larger management ownership levels, management becomes more risk averse and the positive relation between bond returns and management ownership may become weaker or, beyond a certain level, even switch. The study reports a significantly positive relation between management ownership and bond return premia in the 5–25% ownership range and a weak evidence for a nonpositive relation when ownership exceeds 25%.

Anderson et al. (2003) find a piecewise linear relation between founding family ownership and the cost of debt, with one breakpoint at 12% ownership stake. Family firms with less than 12% ownership stakes enjoy about a 42.9 basis point lower cost of debt financing than non-family firms. For high family ownership firms, the study shows an incremental increase in debt costs of 21.1 basis points, suggesting that large family holdings might lead to wealth expropriation from bondholders or that families entrench themselves at the expense of other claimants. Using a quadratic specification, the study finds evidence of a similar curvilinear relation between family ownership and the cost of debt financing. Ortiz-Molina (2006) finds that the relationship between managerial ownership and borrowing costs of corporate bonds is positively related but weaker at higher levels of managerial ownership. The relationship between managerial ownership and borrowing costs is increasing and concave. These results indicate that when top managers hold higher levels of ownership, they are more risk averse and borrowing costs will decline, suggesting that managerial ownership sharpens risk-shifting incentives.

Event risk covenants (ERC) in debt issues could reduce shareholder-bondholder conflicts (Bae et al., 1994) or entrench managers (Cook and Easterwood, 1994). Roth and McDonald (1999) find that the announcement return associated with a debt issue is positively related to management ownership in the 0–5% range and negatively related to the interaction variable between management ownership in the 0–5% range and a PUT dummy that equals one if the debt issue includes a poison put and zero otherwise. The other two ownership segments (5–25% and >25%) and the interaction between these segments and the PUT dummy are not significant. This suggests that as management ownership increases through a low range of ownership (<5%), shareholders respond more favorably to debt announcements, but they suffer from the use of poison puts. The authors argue that their results support the entrenchment view of ERCs.

73.2.5 Corporate Cash Holdings

Opler et al. (1999) examine the agency explanations for corporate cash holdings, in addition to other possible determinants. They suggest that if holding cash is costly and managerial ownership helps align management and shareholders' interests, then cash holdings are expected to fall with management ownership. However, managerial ownership may also protect management against market discipline. To the extent that managerial ownership makes management more risk averse, one would expect cash holdings to increase with managerial ownership. Using piecewise regression model with break points of 5% and 25% insider ownership, the authors find that management ownership has a positive effect on cash holdings for low ownership (<5%), but the relation is not significant for the intermediate and high ownership ranges. Their results are consistent with managerial risk aversion.

73.2.6 Corporate Investment Decisions

Allen and Cebenoyan (1991) apply a switching regression model to examine bank acquisitions and ownership structure. The switching variables are insider shareholdings, α, and shareholder concentration, γ. They find positive bidder returns only for firms with high levels of both α and γ. They find a significant entrenchment effect for high α, low γ firms. Using a quadratic specification, Subrahmanyam et al. (1997) find that bidder returns in bank acquisitions are associated only with high levels of insider ownership. Loderer and Martin (1997) apply a simultaneous equation methodology and find no relation, linear or nonlinear, between executive ownership and bidder returns or between executive ownership and the acquiring firm's Tobin's Q.

In an OLS regression model, Cho (1998) finds that the relation between investment (capital expenditure or research and development expenditure) and insider ownership is positive for ownership levels below 7%, negative for levels

between 7% and 38%, and positive for levels above 38%. However, there is no evidence of nonlinearity in a simultaneous equation framework. In addition, the results show that investment affects corporate value which, in turn, affects ownership structure. This is in contrast to the earlier works by Morck et al. (1988) and others that suggest that ownership structure affects corporate value.

Denis et al. (1997a) show that the level of diversification is negatively related to managerial ownership and outside blockholdings. Using a quadratic term for managerial ownership, they find some evidence of nonlinearity in the relation between the level of diversification and managerial ownership. They find little evidence that the value loss from diversification is related to either managerial or outside blockholder ownership.

Lin and Su (2008) examine the relationship between industrial diversification and firm valuation in China. They regress Tobin's Q on diversification dummy, ownership concentration, and square of ownership concentration. The coefficients on ownership concentration and square of ownership concentration are significantly negative and positive, respectively. The results indicate that the relationship between ownership concentration and Tobin's Q is nonlinear and U-shaped. They also show that Tobin's Q for government-controlled diversified firms is lower than non-government-controlled diversified firms, consistent with the political cost hypothesis of diversification.

Thomas (1995) investigates the nonlinear effects of ownership structure on the hiring of advisors in merger and acquisition transactions. They use the same 5% and 25% turning points for each of the three separate ownership measures (institutional ownership, insider ownership, and 5% blockholdings) in a single logistic regression. The study finds that institutional ownership increases the propensity of firms to hire M&A advisors. The effect is nonlinear in institutional ownership.

Martin (1996) and Ghosh and Ruland (1998) examine the method of payment in corporate acquisitions. Using break points of 5% and 25% managerial ownership in a logistic piecewise linear regression model, Martin (1996) shows that the acquirer's management ownership is not related to the probability of stock financing over small and large ranges of ownership, but is negatively related over a middle range. The results suggest that over an intermediate range of acquirer's managerial ownership, managers may be concerned about their control of the firm, and hence, increases in ownership lead to a lower likelihood of stock financing. Ghosh and Ruland (1998) argue that target's managers with low ownership in their firm are less likely to obtain significant influence in the combined firm even if stock financing is used. However, when their ownership exceeds certain level, there is a greater potential for them to exert significant influence in the combined firm as a major shareholder, and hence, the incidence of stock financing is

expected to be higher as their ownership increases. The authors examine two segments of target's managerial ownership with a single break point of 3% and find evidence supporting their prediction.

Nonlinear relation is also reported in antitakeover provisions research. McWilliams (1990) shows that antitakeover rules benefit shareholders of firms with low managerial ownership (<10%) by providing management with additional bargaining power, whereas for firms with high managerial ownership, antitakeover rules can harm shareholders by entrenching management. Boyle et al. (1998) suggest that insiders can obtain protection from hostile takeover bids either directly via antitakeover provisions or indirectly via higher ownership. They examine the simultaneous determination of insider ownership and takeover protection using data from mutual savings and loans associations converting to stock form. They find that insider ownership is negatively related to the number of extraordinary antitakeover provisions at low levels of insider ownership (<10.3%), but the relation is not significant at higher levels of insider ownership.

73.2.7 Board Structure and Activity

Byrd and Hickman (1992) find a curvilinear relationship between bidding firms' abnormal returns and the proportion of independent outside directors on the board. The relation is positive over most of the range, but is significantly negative when independent outside directors hold a very high proportion of board seats, which implies that having too many independent outside directors may have a negative impact on firm value.

Denis et al. (1997b) show that the probability of top executive turnover is significantly less sensitive to performance when officers and directors own between 5% and 25% of the firm's shares than when they own less than 5%. The results suggest that managers become entrenched at higher ownership levels.

Rosenstein and Wyatt (1997) study the stock-market reaction to announcements of inside managers being appointed to corporate boards. They find that the abnormal return is significantly negative when inside directors own less than 5% of the firm's common stock, significantly positive when their ownership is between 5% and 25%, and insignificantly different from zero when ownership exceeds 25%. The authors argue that at low levels of insider ownership, the addition of an inside director is likely to be an attempt to entrench existing management. At moderate levels of insider ownership, where managerial interests are more closely aligned with those of the outside shareholders, the benefits of having an inside manager's specialized knowledge outweigh the costs of managerial entrenchment.

Yermack (1996) finds that firm value (proxied by Tobin's Q) is negatively related to log of board size, which is consistent with the notion that board effectiveness suffers when the number of directors increases. The log form of the board size implies a convex relation, which the study confirms by using piecewise linear models and regressions against board size and board size squared.

Vafeas (1999) investigates the relation between board meeting frequency and firm performance. While there is a significantly negative relation between firm value and log of board meeting frequency in an OLS regression, the relation becomes insignificant in two-stage least squares (2SLS) regression in which log of board meeting frequency is endogenous. In both the OLS and 2SLS regressions, the study finds a quadratic relation between firm value and insider ownership.

Andres and Vallelado (2008) estimate the relationship between characteristics of board and performance in large international commercial banks. They find that the relationship between board size and performance is inverted U-shaped, implying a positive relationship up to a certain level of board size and a negative impact then. They also report an inverted U-shaped relationship between performance and the proportion of non-executive directors. These findings indicate a trade-off between the advantages of monitoring of board and advising of outside directors. Coles et al. (2008) examine the relationship between firm performance, board size, and board composition. They report a positive (negative) relationship between Tobin's Q and board size for complex (simple) firms.

73.2.8 Risk-Taking Behavior of Financial Institutions

Several studies have examined ownership structure and risk-taking behavior of financial institutions. An example is the paper by Cebenoyan et al. (1995). For 1988, which is a period of regulatory leniency on savings and loans (S&L) closures, the authors find a quadratic relation between insolvency risk and managerial ownership, with a turning point at around 25% managerial ownership. At low managerial ownership levels, as managerial ownership rises, S&Ls exhibited lower insolvency risk, suggesting that managers act to protect their undiversifiable unemployment risk. At higher managerial ownership, managers appear to have engaged in greater risk-taking behavior. In contrast, for 1991, which is a period of regulatory stringency, the study finds a significant linear relation between insolvency risk and managerial ownership, suggesting greater risk-reducing behavior for S&Ls with a larger managerial ownership. This study shows that the functional form of the relation may depend on the regulatory environment.

73.2.9 Relationship Among Price Per Share, Dividend Per Share, and Retained Earnings Per Share

Lee (1976) developed a generalized functional form (GFF) to determine the relationship among the stock price, dividends and retained earnings. He found that the linear form (sometimes even the logarithmic linear form) is not a correct functional form for investigating the dividend effect of the electric utility industry. Moreover, the dividend effect is not significantly different from the retained earning effect for 60% of the cross-section results after the true functional relationship has been determined. Essentially, the GFF explicitly takes the interrelation between dividends and retained earnings into account; the functional form parameter also reflects the different relationship among the stock price, dividends and retained earnings under different economic conditions. In sum, it has been established that the previous studies of determining the dividend effect of the electric utility industry may have pre-judged an important issue-the correct functional form. While linear and logarithmic forms are easy to handle, this consideration alone is not enough to justify employment of either of these forms. In fact, it has been shown that there exists a generalized functional form which allows a compact analysis of the effects of choice of functional form on determining the dividend effect of the electric utility industry.

Chang and Lee (1977) use two alternative techniques to analyze pooled time-series and cross-section data to test the importance of firm effect and time effect in the financial analysis. Their techniques are also integrated with the functional form parameter estimation method to show the importance of appropriate functional form in handling a pooled time-series and cross-section type econometric model. The data on the electric industry show that both the time effect and cross-section effect are of importance in explaining stock price variation. It is also found that linear form (and/or) log-linear form is not always appropriate in testing the importance of both time effect and firm effect in financial analyses.

73.3 Model Specifications in Existing Studies

In this section, we summarize the empirical models used to estimate nonlinear relations. The notations used are as follows: y_i is the dependent variable; z_i is the independent variable that is hypothesized to have a nonlinear relation with the dependent variable; and $x_{i1}, ..., x_{ik}$ are the k control variables. Table 73.1 provides a list of examples of papers that have used the various models.

Table 73.1 Nonlinear models in corporate finance research

[a]Yermack (1996) uses piecewise linear and quadratic models as robustness checks on his log-linear model relating board size to firm value

73.3.1 The MSV Piecewise Regression Model

The MSV piecewise regression model can be generalized as follows[8]:

$$y_i = \alpha_i + \beta_1 x_{i1} + \cdots + \beta_k x_{ik} + \theta_1 z_{i1} + \cdots + \theta_p z_{ip} + \varepsilon_i, \quad i = 1, \ldots, n \tag{73.1}$$

where the piecewise variables, $z_{i1}, \cdots, z_{ip}$, are defined as follows:

$$z_{i1} = \begin{cases} z_i, & \text{if } z_i < P_1 \\ P_1, & \text{otherwise} \end{cases}$$

$$z_{ij} = \begin{cases} 0, & \text{if } z_i < P_{j-1} \\ z_i - P_{j-1}, & \text{if } P_{j-1} \le z_i < P_j, \\ P_j - P_{j-1}, & \text{if } P_j \le z_i \end{cases} \quad j = 2, \cdots, p-1$$

$$z_{ip} = \begin{cases} 0, & \text{if } z_i < P_{p-1} \\ z_i - P_{p-1}, & \text{otherwise} \end{cases}$$

The piecewise linear relation is assumed to have $p - 1$ break points, $P_1, P_2, \cdots, P_{p-1}$.

In order to apply the MSV methodology, the number and positions of the turning points have to be pre-determined. Apart from Morck et al. (1988), in which a model with seven break points is reported as one of the specification tests, most other studies assume two turning points. Further, while Morck et al. (1988) and Wruck (1989) report results on turning points other than the 5% and 25% ownership level, most subsequent ownership papers assume the same turning points of 5% and 25% without further specification checks. The 5% and 25% break points have more or less become 'standard' in ownership research even though the definitions of ownership variables in various studies may differ. For example, Morck et al. (1988) use percentage ownership of members of the board of directors. Wruck (1989) and Hertzel and Smith (1993) define their ownership variable as the share ownership of managers, directors, and 5% or greater beneficial owners. McConnell and Servaes (1990), Hudson et al. (1992), and Bagnani et al. (1994) use insider ownership. Martin (1996) includes stock options in the calculation of ownership of officers and directors. Finally, Thomas (1995) uses the same 5% and 25% turning points for institutional ownership, insider ownership and 5% block ownership in the same regression.

We observe that different models use different sets of control variables. The influence of control variables on the signs and significance levels of the piecewise variables is highlighted in Table 73.2 of Morck et al. (1988), which shows that without the control variables, the relation between Tobin's Q and board ownership when ownership is over 25% is insignificantly negative. When control variables such as R&D expenses per dollar of assets are included the relation becomes weakly significantly positive.

The model used in Wruck (1989) is a modified MSV piecewise regression model in which the first differences in variables are used:

$$\Delta y_i = \alpha_i + \beta_1 x_{i1} + \cdots + \beta_k x_{ik} + \theta_1 \Delta z_{i1} + \cdots + \theta_p \Delta z_{ip} + \varepsilon_i,$$
$$i = 1, \ldots, n$$

$$(73.2)$$

The piecewise variables, $\Delta z_{i1}, \cdots, \Delta z_{ip}$ are defined as $\Delta z_{ij} = z^{(a)}_{ij} - z^{(b)}_{ij}$, where $z^{(b)}_{ij}$ and $z^{(a)}_{ij}$ are values of z_{ij} before and after an event and are defined analogously as the z_{ij} piecewise variables in the MSV model (Equation 73.1).

It is interesting to note that when Wruck (1989) takes the first difference of Morck et al.'s (1988) piecewise regression

Table 73.2 Cross-sectional regression of research and development expenditure: estimation of Equation 73.20

Independent variables	Coefficient	T-ratio	P-value (%)
Constant	0.0081	0.963	33.6
EVS	0.0107	3.388	0.1
CFS	−0.0015	−0.101	92.0
LTD	−0.0055	−0.691	49.0
SIZE	0.0016	1.348	17.8
ADVS	−0.0075	−0.205	83.8
BLOC	0.0065	0.782	43.5
INST	0.0126	0.993	32.1
Industry dummies (IND$_1$ to IND$_{14}$)	Yes		
INSD	0.0095	1.039	29.9

Note: The dependent variable is research and development expenditure divided by sales (*RDS*). The independent variables are defined as follows

EVS	= (Market value of equity + book value of long-term debt – book value of total assets)/sales
CFS	= Free cash flow divided by sales, where free cash flow equals operating income before depreciation – interest expense – taxes – dividends
LTD	= Long-term debt/(long-term debt + market value of equity)
SIZE	= Log(market value of equity)
ADVS	= Advertising expenses divided by sales
BLOC	= Blockholders' share of common equity in % (excluding insiders' blockholdings)
INST	= Institutional holdings in % (excluding institutional blockholdings)
IND$_1$ to IND$_{14}$	= Industry dummies
INSD	= Insider holdings in %

results to compare with her own results (see Table 7 in Wruck), she implicitly assumes that the control variables in Morck et al. model would disappear. This assumes that the values and the coefficients of the control variables remain unchanged before and after a private placement.

In another study of private placements by Hertzel and Smith (1993), the piecewise ownership variables as defined in Wruck (1989) are not significant. Hertzel and Smith explain that the contrasting results may be due to the smaller average firm size in their sample relative to that of Wruck (1989). However, it should be noted that Hertzel and Smith (1993) include information variables such as book-to-market-equity in their models, which are not examined in Wruck (1989). They show that the information variables may have

dominated the ownership variables. We suggest that the different results may be influenced by different control variables in the two studies.

Thomas (1995), Martin (1996), and Ghosh and Ruland (1998) adapted the MSV piecewise linear methodology in a logistic regression framework. Again, the issue of the number and positions of the turning points arises in these studies.

73.3.2 Models with Slope Dummies

Models with slope dummies to capture nonlinear effects are common in empirical studies.[9] The following is a general representation of a model with slope dummies.

$$y_i = \alpha_i + \beta_1 x_{i1} + \cdots + \beta_k x_{ik} + \theta_1 D_1 z_i + \cdots + \theta_p D_p z_i + \varepsilon_i,$$
$$i = 1, \ldots, n$$

$$(73.3)$$

where $D_1 = 1$ if $z_i < P_1$, and 0 elsewhere; $D_j = 1$ if $z_i \in [P_{j-1}, P_j)$, and 0 elsewhere, for $j = 2, \ldots, p-1$; and $D_p = 1$ if $z_i \geq P_{p-1}$, and 0 elsewhere.

The slope dummy approach does not require that the various segments meet at the joint points, P_1 to P_{p-1}. This may be a more flexible model than the MSV piecewise regression model. However, researchers must decide whether there is any theoretical justification for discontinuities at the joint points. Similar to the MSV methodology, the slope dummy variables approach assumes known number and positions of the break points.

73.3.3 Quadratic and Higher Order Polynomial Regression Models

The quadratic regression model used in numerous studies can be represented as follows:

$$y_i = \alpha_i + \beta_1 x_{i1} + \cdots + \beta_k x_{ik} + \theta_1 z_i + \theta_2 z_i^2 + \varepsilon_i, \ i = 1, \ldots, n$$
$$(73.4)$$

The main advantage of the quadratic regression model over the MSV methodology is that the turning point is determined empirically. However, the quadratic model assumes that there is only one turning point. Further, it may not fit the data well if the nonlinear relationship is not smooth. Finally, the position of the turning point is sensitive to the inclusion of other variables in the model (as seen in McConnell and Servaes, 1990).

The quadratic regression model does not allow for multiple turning points. Since Morck et al. (1988) and Wruck (1989) suggest that there may be more than one turning

point in the relationship between firm value and ownership variables, a higher order polynomial may be more appropriate. Short and Keasey (1999) indeed find a significant cubic functional relation between firm performance and managerial ownership for a sample of UK firms. Thus, as part of specification checks, it is important for researchers to examine higher order polynomial functional form. We discuss below a case where a cubic functional form (or a piecewise linear model) may be more appropriate. As discussed in Section 73.2.3 above, Schooley and Barney (1994) find a curvilinear relation between dividend yield and CEO stock ownership. The relation is negative below 15% ownership but is positive above the turning point. The authors argue that the positive relation above 15% ownership can be explained by the notion that higher dividend payout can increase market scrutiny on the firm when management is perceived to be entrenched at a sufficiently high ownership level. Since the piecewise linear results in Morck et al. (1988) and Wruck (1989) show that the alignment-of-interests effects dominate the entrenchment effects when ownership is above 25%, there may be another negative relation between dividend yield and CEO ownership at a higher ownership level.

The different model specifications in Slovin and Sushka (1993) and Wruck (1989) provide an interesting comparison. Slovin and Sushka (1993) report a quadratic relation between abnormal return at the announcement of the death of an insider blockholder and the *level* of inside blockholding, while Wruck (1989) finds a piecewise linear relation between abnormal return associated with private placement announcements and *change* in ownership concentration. Slovin and Sushka (1993) report that deaths of inside blockholders generally reduce ownership concentration. It would be interesting to examine whether the *reduction* in ownership concentration following the deaths of inside blockholders can explain the abnormal return by using Wruck's (1989) piecewise linear specification. Since the functional form for the change in firm value (as proxied by abnormal return) depends on the functional form of the firm value itself, the results of the two studies suggest some conflicting evidence on the impact of corporate ownership structure on firm value.

73.3.4 The Fields and Mais' Model

Fields and Mais (1994) provide an alternative method of examining nonlinear relationship. They regress the slope of a function against the independent variable as follows:

$$\frac{\Delta y_i}{\Delta z_i} = \alpha_i + \beta_1 x_{i1} + \cdots + \beta_k x_{ik} + \theta_1 z_i + \varepsilon_i, \ i = 1, \ldots, n$$

$$(73.5)$$

The dependent variable is the ratio of announcement-period abnormal return to change in management ownership. This model implicitly assumes that the relation between firm value (y_i) and management ownership (z_i) is quadratic. A significant relation between $\Delta y_i / \Delta z_i$ and z_i implies a curvilinear relation between y_i and z_i. Since the implicit model is a quadratic one, this methodology cannot accommodate multiple turning points.

73.3.5 Switching Regression Models

Allen and Cebenoyan (1991) use a switching regression model to examine structural changes in the relationship between bank acquisition and ownership structure.[10] Their model has the following general form:

$$y_i = \alpha_i + \beta_{1j}x_{i1} + \cdots + \beta_{kj}x_{ik} + \theta_{1j}z_{1i} + \cdots$$
$$+ \theta_{pj}z_{pi} + \varepsilon_i \qquad (73.6)$$

where $z_{1i}, \cdots, z_{pi}$ are the p switching variables, $j =$ I, II, III, IV, . . ., are the regimes determined by the critical point(s) of the switching variables, and $x_{i1}, ..., x_{ik}$ are the k control variables. In Allen and Cebenoyan, the switching variables are the fraction of shares held by insiders and the fraction of shares held by the top five shareholders. Pantzalis et al. (1998) apply a similar switching regression model to examine the relationship between market valuation of a firm and its equity ownership structure. The switching variables used are the percent of shares owned by insiders and the percent of shares owned by blockholders. Note that Allen and Cebenoyan (1991) and Pantzalis et al. (1998) use two switching variables. With one switching point for each variable, there are four regimes. In Equation 73.6 above, we are allowing more than two switching variables and hence there could be more than four regimes.[11]

The advantage of the switching regression model is that it does not impose a constant relationship between the switching variables and the dependent variable across different regimes. Furthermore, the critical values of the switching variables are endogenous, i.e., they are not pre-specified. However, the switching regression model has the same problem as the model with slope dummies in that various segments do not join.

73.3.6 Simultaneous Equation Model

Several researchers use simultaneous equation model in corporate finance research (see Boyle et al., 1998; Cho, 1998; Himmelberg et al., 1999). The need to use simultaneous equation model arises from the notion that insider ownership or other variables may be endogenous, instead of exogenously determined. Boyle et al. (1998) examine a model where the number of antitakeover provisions and insider ownership are considered as endogenous variables. Cho's (1998) model assumes that insider ownership, corporate value and investment are endogenous. Himmelberg et al. (1999) apply the model to panel data where time series and cross-section observations are pooled.

A simple simultaneous equation model involving two endogenous variables can be represented by the following equations:

$$y_{i1} = \alpha_1 + \delta_1 y_{i2} + \beta_{11}x_{i1} + \cdots + \beta_{1k}x_{ik} + u_{i1} \qquad (73.7)$$

$$y_{i2} = \alpha_1 + \delta_2 y_{i1} + \beta_{21}x_{i1} + \cdots + \beta_{2k}x_{ik} + u_{i1} \qquad (73.8)$$

If we estimate a single equation like Equation 73.7 ignoring the fact that y_2 is endogenous, then the estimator can be shown to be biased. Therefore, in the estimation the fact that both y_1 and y_2 are endogenous needs to be incorporated. In practice, the estimation is usually done by applying the two-stage least squares estimation technique, which involves the use of instrumental variables.

The simultaneous equation model can accommodate nonlinear effects as discussed before in a single equation setup. For example, y_2 may be piecewise linear or quadratic. The discussions on the advantages and disadvantages of the various nonlinear specifications are also relevant to a simultaneous equation setup.

73.4 Extensions

In this section, we provide two possible extensions to the exiting methodologies used in detecting nonlinear relationship in corporate finance research: "residual analysis" and "nonlinearity with interaction effect."

73.4.1 Residual Analysis

It is a well-established fact that a partial regression coefficient, in a multiple regression framework, can be obtained by running the regression of residuals. Consider the following regression equation:

$$y_i = \beta_1 x_{i1} + \cdots + \beta_k x_{ik} + \theta_1 z_{i1} + \cdots + \theta_p z_{ip} + \varepsilon_i,$$
$$i = 1, \ldots, n$$
$$(73.9)$$

In matrix notation, the regression equation can be represented by

$$Y = X\beta + Z\theta + \varepsilon \qquad (73.10)$$

where

$$Y = \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_n \end{bmatrix}, \quad X = \begin{bmatrix} x_{11} & x_{12} & \cdots & x_{1k} \\ x_{21} & x_{22} & \cdots & x_{2k} \\ \vdots & \vdots & \cdots & \vdots \\ x_{n1} & x_{n2} & \cdots & x_{nk} \end{bmatrix},$$

$$Z = \begin{bmatrix} z_{11} & z_{12} & \cdots & z_{1p} \\ z_{21} & z_{22} & \cdots & z_{2p} \\ \vdots & \vdots & \cdots & \vdots \\ z_{n1} & z_{n2} & \cdots & z_{np} \end{bmatrix},$$

$$\beta = \begin{bmatrix} \beta_1 \\ \beta_2 \\ \vdots \\ \beta_k \end{bmatrix}, \quad \theta = \begin{bmatrix} \theta_1 \\ \theta_2 \\ \vdots \\ \theta_p \end{bmatrix}, \quad \text{and} \quad \varepsilon = \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \vdots \\ \varepsilon_n \end{bmatrix}.$$

Suppose that we are interested in the parameter vector θ. We can obtain θ by estimating the regression Equation 73.9. Alternatively, we can estimate θ by running the following regression:

$$MY = MZ\theta + u \qquad (73.11)$$

where $M = I_n - X(X'X)^{-1}X'$ is an idempotent matrix, and $MY = Y - X(X'X)^{-1}X'Y$ and $MZ = Z - X(X'X)^{-1}X'Z$ are the residual vectors of the auxiliary regression Equations 73.12 and 73.13 respectively, as given below:

$$Y = X\Phi_1 + U_1 \qquad (73.12)$$

$$Z = X\Phi_2 + U_2 \qquad (73.13)$$

Therefore, regression Equation 73.11 is the regression of the residuals of regression Equation 73.12 on the residuals of regression Equation 73.13.

Regression Equation 73.11 has the advantage that it represents the regression of Y on Z after the linear impact of X is removed from both Y and Z.[12] This is what we would like to achieve when introducing control variables in a regression relationship. For example, if we use X to represent the control variables, then regression (73.11) represents the relationship between Y and Z after eliminating the linear effect of the control variables. One advantage of using Equation 73.11 is a reduction in dimensionality. Graphical visualization is also made easier. For example, when Z consists of a single variable (e.g., insider ownership where Y represents firm value), Equation 73.11 would represent the relationship between two variables where two-dimensional graphical visualization is possible.

Since the variables used in auxiliary regression (73.11) are residuals, we call the analysis "residual analysis." The residual analysis can be applied to examine several types of

nonlinear relationships. Consider a case where Z consists of a single variable denoted by z and the relationship is a quadratic one as given below:

$$y_i = \beta_1 x_{i1} + \cdots + \beta_k x_{ik} + \theta_1 z + \theta_2 z^2 + \varepsilon_i \qquad (73.14)$$

Then, the relationship in residual form can be written as

$$MY = MZ_1\theta_1 + MZ_2\theta_2 + u \qquad (73.15)$$

where $Z_1 = \begin{bmatrix} z_1 \\ z_2 \\ \vdots \\ z_n \end{bmatrix}$ and $Z_2 = \begin{bmatrix} z_1^2 \\ z_2^2 \\ \vdots \\ z_n^2 \end{bmatrix}$

Therefore, the quadratic relationship, in the presence of control variables, can be estimated using the residual regression.

The residual regression can also be applied to a switching regression with known switching points. Consider the following regression, with switching point at d_1:

$$y_i = \beta_1 x_{i1} + \cdots + \beta_k x_{ik} + \theta_1 z + \theta_2 D(z, d_1)z + \varepsilon_i \quad (73.16)$$

where $D(z, d_1)$ is a dummy variable defined as $D(z, d_1) = \begin{cases} 0, & \text{for } z < d_1 \\ 1, & \text{for } z \geq d_1 \end{cases}$. Then, the residual regression is given by

$$MY = MZ_1\theta_1 + MZ_{d_1}\theta_2 + u \qquad (73.17)$$

where Z_1 is defined as before and Z_{d_1} is the vector representation of the variable $D(z, d_1)z$.

In general, any nonlinear relationship can be estimated using the residual method so long as the relationship is linear in parameters. Furthermore, in the residual analysis the grid search technique can be used to find the unknown switching points in a switching regression. Due to the reduction in dimensionality, the residual analysis is computationally efficient when there is a need to estimate the model many times. For example, when using grid search technique in estimating switching points, the model needs to be estimated many times. In this case, the residual analysis will be computationally efficient. Finally, it is important to note that the residual analysis can be applied to the simultaneous equation model with some minor modifications.

73.4.2 Nonlinearity with Interaction Effect

Even though nonlinear models are widely applied in corporate finance research, the interaction effect seems to be less well researched. However, interaction effects can be quite

important. For example, in the analysis of the effect of the insider ownership on the firm value, it might be important to look at the interaction effect of the institutional ownership.[13]

Morck et al. (1988) show that when insider ownership is very low, the alignment effect plays an important role. However, after a certain level of insider ownership, the entrenchment effect will dominate. Eventually, at very high levels of the insider ownership, the alignment effect will again dominate. However, it is possible that when the level of institutional ownership is high, the managerial entrenchment effect could be reduced significantly because of the monitoring effect of institutional ownership. This could result in a situation where the entrenchment effect will never dominate the alignment effect.

Allen and Cebenoyan (1991) analyze interaction effects of two ownership variables (insider shareholdings and shareholder concentration) using a switching regression methodology. We can also analyze interaction effects using models that explicitly incorporate the interaction effect. One example of the models is given below[14]:

$$
\begin{aligned}
y =\, & \beta_1 x_1 + \cdots + \beta_k x_k + \theta_1 z_1 + \theta_2 z_1^2 + \theta_3 z_1^3 + \gamma_1 z_1 z_2 + \gamma_2 z_1 z_2^2 \\
& + \varphi_1 z_2 + \varphi_2 z_2^2 + \varphi_3 z_2^3 + e
\end{aligned}
$$

$$(73.18)$$

As before, $x_i{}'$s represent the control variables. In this model, we are mainly interested in the effect of z_1 on y. Coefficients γ_1 and γ_2 represent the interaction effect of z_1 and z_2. This allows the effect of z_1 on y to be nonlinearly dependent on z_2. This is clear from the partial derivative of y with respect to z_1:

$$
\frac{\partial y}{\partial z_1} = \theta_1 + 2\theta_2 z_1 + 3\theta_3 z_1^2 + \gamma_1 z_2 + \gamma_2 z_2^2 \qquad (73.19)
$$

This model allows the sign of the partial derivative of y with respect to z_1 to change depending on the value of z_2. One possible application of such model would be to analyze the effect of insider ownership (z_1) and institutional ownership (z_2) on the value of the firm (y).

As in the switching regression model, our "nonlinearity with interaction effect" method does not impose a constant relationship between the switching variables and the dependent variable across different regimes. Furthermore, the critical values of the switching variables are endogenous. In addition, our method has several advantages relative to the switching regression model. Our method allows a smooth transition from one segment to another segment (see Figure 73.1 in the next section). It allows the interaction effect to be smooth.[15] Finally, by including a higher order polynomial our method can allow more than one turning point. The above approach to accommodate nonlinear interaction effects can also be implemented in a simultaneous equation framework.

73.5   Empirical Analysis

73.5.1   Application of Residual Analysis

In this section, we will apply the residual analysis in the estimation of the nonlinear dependence of R&D investment on the insider ownership.[16] We will estimate three versions of the investment function: (1) with no switching point, (2) with one switching point, and (3) with two switching points. In Equation 73.20, only the linear effect of insider ownership is included. In Equation 73.21, a piecewise linear function with one switching point (I_1) is used to express the nonlinear effect of insider ownership. Equation 73.22 shows a piecewise linear function with two switching points (I_1 and I_2).[17] The data set used in this analysis is the same as that used in Pantzalis et al. (1998).[18] All data are end-of-year data for 1987.

With no switching point:

$$
\begin{aligned}
RDS =\, & \beta_0 + \beta_1 EVS + \beta_2 CFS + \beta_3 LTD + \beta_4 SIZE + \beta_5 ADVS \\
& + \beta_6 BLOC + \beta_7 INST + \sum_{j=1}^{14} \beta_{7+j} IND_j + \theta INSD + Error
\end{aligned}
$$

$$(73.20)$$

With one switching point:

$$
\begin{aligned}
RDS =\, & \beta_0 + \beta_1 EVS + \beta_2 CFS + \beta_3 LTD + \beta_4 SIZE \\
& + \beta_5 ADVS + \beta_6 BLOC + \beta_7 INST + \sum_{j=1}^{14} \beta_{7+j} IND_j \\
& + \theta_1 INSD_1 + \theta_2 INSD_2 + Error
\end{aligned}
$$

$$(73.21)$$

where

$$
INSD_1 = \begin{cases} INSD, & \text{if} \quad INSD < I_1 \\ I_1, & \text{if} \quad INSD \ge I_1 \end{cases},
$$

and

$$
INSD_2 = \begin{cases} 0, & \text{if} \quad INSD < I_1 \\ INSD - I_1, & \text{if} \quad INSD \ge I_1 \end{cases}.
$$

EVS = (market value of equity + book value of long-term debt -book value of total assets)/sales

INSD = insider holdings in %

BLOC = blockholders' share of common equity in % (excluding insiders' blockholdings)

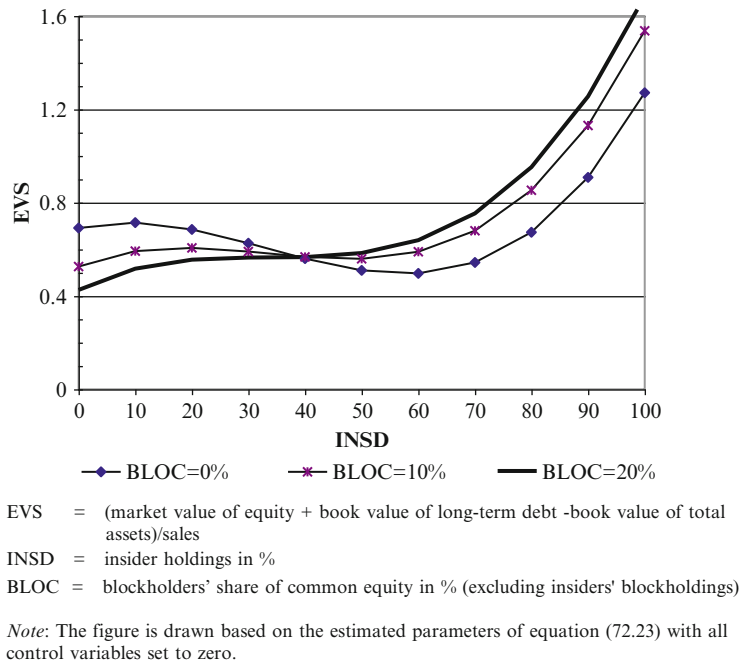
Note: The figure is drawn based on the estimated parameters of equation (72.23) with all control variables set to zero.


Fig. 73.1 Interaction effect of block ownership on the nonlinear relationship between firm value and insider ownership

With two switching points:

$$RDS = \beta_0 + \beta_1 EVS + \beta_2 CFS + \beta_3 LTD + \beta_4 SIZE + \beta_5 ADVS$$
$$+ \beta_6 BLOC + \beta_7 INST + \sum_{j=1}^{14} \beta_{7+j} IND_j + \theta_1 INSD_1$$
$$+ \theta_2 INSD_2 + \theta_3 INSD_3 + Error$$

$$(73.22)$$

where

$$INSD_1 = \begin{cases} INSD, & \text{if} \quad INSD < I_1 \\ I_1, & \text{if} \quad INSD \geq I_1 \end{cases}$$

$$INSD_2 = \begin{cases} 0, & \text{if} \quad INSD < I_1 \\ INSD - I_1, & \text{if} \quad I_1 \leq INSD < I_2 \\ I_2 - I_1, & \text{if} \quad INSD \geq I_2 \end{cases}$$

$$INSD_3 = \begin{cases} 0, & \text{if} \quad INSD < I_2 \\ INSD - I_2, & \text{if} \quad INSD \geq I_2 \end{cases}$$

The variable definitions are as follows:

RDS	=	R&D expenditures divided by sales
EVS	=	(Market value of equity + book value of long-term debt - book value of total assets)/sales
CFS	=	Free cash flow divided by sales, where free cash flow equals operating income before depreciation – interest expense – taxes – dividends
LTD	=	Long-term debt/(long-term debt + market value of equity)

(continued)

SIZE	=	Log(market value of equity)
ADVS	=	Advertising expenses divided by sales
BLOC	=	Blockholders' share of common equity in % (excluding insiders' blockholdings)
INST	=	Institutional holdings in % (excluding institutional blockholdings)
IND_1 to IND_{14}	=	Industry dummies
INSD	=	Insider holdings in %

It is important to note that the switching points in Equations 73.21 and 73.22 are estimated rather than pre-determined. The locations of switching points are estimated using the grid search technique. The number and locations of switching points are chosen based on the log likelihood function.

Table 73.2 summarizes the results of the estimation of Equation 73.20. The results show that only *EVS* (a proxy for Tobin's Q) is significant. All other variables, including the insider ownership (*INSD*), are not significant. From the likelihood ratio test, as reported in Table 73.3, there is strong evidence of one switching point. The likelihood ratio statistic for two switching points is insignificant, indicating a single switching point.

Table 73.4 summarizes the results of the estimation of Equations 73.21 and 73.22. The single switching point in Equation 73.21 is found to be at 10.7% insider ownership, whereas the two switching points in Equation 73.22 are at 12.6% and 19.7% insider ownership. The results from the estimation of Equation 73.21 show that R&D investment

Table 73.3 Log likelihood ratio test in determining the number of switching points

	Log likelihood function	Likelihood ratio statistic	P-value (%)
No switching point	1130.05		
Single switching point at 10.7% insider ownership	1135.71	11.32	0.08
Two switching points at 12.6% and 19.7% insider ownership	1136.42	1.42	23.34

Note: This table presents the Log Likelihood Ratio Test in determining the number of switching points in Equations 73.20, 73.21, and 73.22. The log likelihood ratio test statistic is given by $2(Log_e(L_{i+1}) - Log_e(L_i))$ where $Log_e(L_i)$ is the value of the log likelihood function with i number of switching points

Table 73.4 Cross-sectional regression of research and development expenditure: estimation of Equations 73.21 and 73.22

Independent variables	Coefficient	T-ratio	P-value (%)
Estimation of Equation 73.21: single switching point at 10.7%			
$INSD_1$	0.1404	3.530	0.04
$INSD_2$	−0.1210	−1.110	26.70
Estimation of Equation 73.22: two switching points at 12.6% and 19.7%			
$INSD_1$	0.1535	3.565	0.04
$INSD_2$	−0.1172	−1.497	13.44
$INSD_3$	−0.0014	−0.097	92.24

Note: The control variables are the same as the independent variables given in Table 73.2 except the inside ownership (INSD). Since we use residual analysis, the estimation of the coefficients of the control variables is eliminated

increases with the level of insider ownership when insider ownership is below 10.7%. However, for insider ownership above 10.7%, R&D investment does not significantly change with insider ownership. The results from the estimation of Equation 73.22 with two switching points show that R&D investment increases with insider ownership up to the level of 12.6% insider ownership. Beyond 12.6% and up to 19.7% insider ownership, R&D investment decreases with increase in insider ownership. However, this negative relationship is significant only at 15% level. Beyond 19.7% insider ownership, the relationship between insider ownership and R&D investment is insignificant. These results are similar to those obtained by Cho (1998) although the switching points are different, which could be due to the different variables and data sets used. However, since the empirical results suggest that there is only one switching point, our conclusion regarding the R&D investment function should be based on the estimation of Equation 73.21.

73.5.2 Application of Nonlinear Effect with Interaction

As an example of nonlinear effect with interaction, we estimate the relationship between firm value and ownership structure. Specifically, the following equation is estimated:

$$EVS = (\text{control variables}) + \theta_1 z_1 + \theta_2 z_1^2 + \theta_3 z_1^3$$

$$+ \gamma_1 z_1 z_2 + \gamma_2 z_1 z_2^2 + \phi_1 z_2 + \phi_2 z_2^2 + \phi_3 z_2^3 + e \quad (73.23)$$

where $z_1 = INSD$ and $z_2 = BLOC$. The control variables used are *RDS, CFS, LTD, ADVS, INST,* and the 14 industry dummies.

Table 73.5, Figures 73.1 and 73.2 summarize the empirical results of the estimation of Equation 73.23. The results show that the effect of managerial entrenchment exists only for a low level of block ownership. For example, at 10% of block ownership, the entrenchment effect is very small and it completely disappears when the block ownership reaches 20%. Therefore, the evidence suggests that the nonlinear relationship between the insider ownership and firm value depends on the level of block ownership. A high level of block ownership seems to be enough to eliminate the entrenchment effect.

73.6 Concluding Remarks

Nonlinear model specifications are prevalent in extant corporate finance literature. In this paper, we provide a detailed review of the theory and evidence in these studies. We note the diversity in methodologies used to detect nonlinearity in these studies. We then discuss the strengths and weaknesses of each of these methods.

Based on our review, several observations can be made. First, since the work of Morck et al. (1988), the use of piecewise linear regression has become commonplace in corporate finance research, especially when the variable concerned is related to ownership structure. Many of these studies use the 'standard' turning points of 5% and 25% as in Morck et al. (1988) without evidence of specification checks. As shown in Section 73.2, the number and locations of turning points are far from fixed. In fact, our review shows that several papers do report different turning points in the relation between firm value and managerial ownership, both in cross-sectional and event studies. Studies that use the same

Table 73.5 Estimation of Equation 73.23

Independent variables	Coefficient	T-ratio	P-value (%)
Constant	0.691	6.155	0.00
RDS	2.123	3.505	0.05
CFS	−0.115	−0.546	58.51
LTD	−0.978	−9.553	0.00
ADVS	−0.078	−0.152	87.92
INST	0.225	1.593	11.18
Industry dummies (IND_1 to IND_{14})	Yes		
INSD	0.565	0.863	38.86
$INSD^2$	−3.727	−1.730	8.42
$INSD^3$	3.742	1.977	4.86
INSD × BLOC	5.204	2.607	0.94
$INSD \times BLOC^2$	−9.015	−2.204	2.79
BLOC	−2.009	−2.953	0.33
$BLOC^2$	3.787	1.586	11.33
$BLOC^3$	−1.904	−0.897	37.04

Note: The dependent variable is *EVS*, which is defined as (market value of equity + book value of long-term debt – book value of total assets)/ sales. The independent variables are defined as follows

RDS	= R&D expenditures divided by sales
CFS	= Free cash flow divided by sales, where free cash flow equals operating income before depreciation – interest expense – taxes – dividends
LTD	= Long-term debt/(long-term debt + market value of equity)
ADVS	= Advertising expenses divided by sales
INST	= Institutional holdings in % (excluding institutional blockholdings)
IND_1 to IND_{14}	= Industry dummies
INSD	= Insider holdings in %
BLOC	= Blockholders' share of common equity in % (excluding insiders' blockholdings)

turning points as in Morck et al. (1988) may not find significant results for certain segments of the variable. These studies may have suffered from model specification error. Further, we also note that different control variables used in different studies may have an impact on the nonlinear results.

Second, using alternative methodology may provide new insights on issues where mixed results have been previously documented. For example, when managerial ownership is endogenously determined in a simultaneous equation model as in Cho (1998), the relation between managerial ownership and firm value becomes insignificant. Another example is that provided by Halpern et al. (1999) where cluster analysis is used to identify two distinct groups of poorly performing firms going private through leveraged buyouts. They find that the motivations and post-transaction actions of the two groups are different and suggest that the mixed results in previous studies may be due to the mix of LBO firms in the samples.

Third, some studies do not find evidence of nonlinear relation when one is expected. The lack of results may be

due to the methodology used. For example, Mikkelson et al. (1997) find that the post-IPO firm performance is unrelated to insider ownership and insider ownership squared. Lie (2000) does not find evidence supporting the notion that, among firms that have high excess cash and low growth opportunities, the abnormal return associated with announcements of special dividends and self-tender offers should be stronger for those with poor control mechanisms. The author uses the standard 5% and 25% break points for the dummy ownership variable.

Finally, as shown in Cebenoyan et al. (1995) and Short and Keasey (1999), the functional form of nonlinear relation may be dependent on the regulatory or institutional environment. When one examines international data or those related to regulated industries, it is important to explore alternative model specifications or methodologies.

In this paper, we provide two possible methodological extensions to examine nonlinear relationships in corporate finance research. The first method, which is known as residual analysis, uses the auxiliary regression technique. This technique allows the researchers to take away the linear effect of the control variables and concentrate on the residuals that are free of the effect of the control variables. This method, in addition to reducing the dimensionality, makes graphical visualization possible where there are one or two switching variables. This is true regardless of the number of control variables. Furthermore, the residual analysis will be computationally efficient when using grid search technique in finding switching points. As an example, we apply the residual analysis in the estimation of R&D investment function.

The second method involves modeling the interaction effect between variables to test the effect of one switching variable on another switching variable. This method allows a smooth transition from one segment to another segment and enables the interaction effect to be smooth. By including a higher order polynomial, this method also allows more than one turning point. A version of the model with interaction effect is applied in the estimation of the impact of insider ownership on Tobin's Q. We find that the well-known entrenchment effect disappears when the block ownership is sufficiently high.

Notes

1. See, for example, Byrd and Hickman (1992), Bagnani et al. (1994), Opler et al. (1999), Joh (2003) and others.
2. For example, Thomas (1995) uses the same turning points (5% and 25%) for each of the three different ownership measures in a single model.
3. Hudson et al. (1992) show that, after controlling for firm size and earnings to price ratio, the relation between excess returns and insider ownership is negative but insignificant in the 0–5% insider ownership range,
EVS   =   (market value of equity + book value of long-term debt -book value of total
              assets)/sales
INSD =   insider holdings in %
BLOC =   blockholders' share of common equity in % (excluding insiders' blockholdings)

Note: The figure is drawn based on the estimated parameters of equation (72.23) with all
control variables set to zero.

Fig. 73.2 The nonlinear relationship between firm value, insider ownership and block ownership (Note) The figure is drawn based on the estimated parameters of equation (73.23) with all control variables set to zero.

positive but insignificant in the 5–25% range, and significantly positive beyond 25%.

4. Daines (2001) also reports a quadratic relation between director and officer ownership and Tobin's Q. Woidtke (2003) reports a quadratic relation between insider ownership and industry-adjusted Q.

5. An earlier paper by Kole (1995) also examines the differences in data sources used in ownership studies and suggests that differences in firm size can account for the reported differences in results.

6. To allow for a possible nonlinear relation, the authors divide the sample firms into three institutional ownership groups using two methods. The first is the equal-groups method, whereby firms are divided into three equal groups of low, intermediate, and high institutional ownership. The second method splits the sample into three groups using break points of 5% and 30%, which are pre-determined.

7. Lee et al. (1987) propose an integrated model consistent with the practical decision process to characterize the dividend adjustment process. Marquardt's (1963)

nonlinear regression method is used to estimate the parameters of the integrated model. They show that the integrated model better explains the firm's dividend decision process.

8. The term 'piecewise regression' was first used in McGee and Carleton (1970). The MSV piecewise regression model is similar to the linear spline function discussed in Johnston (1984).

9. Kennedy et al. (1992) use the term 'piecewise linear model' to describe a model in which nonlinearity is accommodated by using a set of slope dummies.

10. The switching regression model follows that of Goldfeld and Quandt (1973).

11. One can split a full sample into different regimes by using the cluster analysis as is done in Halpern et al. (1999). The authors hypothesize that there are two types of poorly performing firms going private through leveraged buyout. One group consists of firms in which managers own an insignificant fraction of their firm's stock and are vulnerable to a hostile takeover. The other group consists of firms in which managers own a significant fraction of

their firm's stock and so face little risk of hostile takeover. They use cluster analysis to separate their sample of leveraged buyout firms into two clusters according to managerial ownership and perform analysis on these groups separately. The cluster analysis technique is described in Hartigan and Wong (1979).

12. *MY* represents the component of *Y* remaining after the linear impact of *X* is taken out. Similarly, *MZ* represents component of *Z* after the linear impact of *X* is removed.

13. For example, McConnell and Servaes (1990) show that the inclusion of institutional ownership in the regression model can increase the turning point in the quadratic relation between the inside ownership variable and firm value.

14. Halpern et al. (1999) consider a simplified version of interaction effect where $\theta_2 = \theta_3 = 0$ and $\phi_1 = \phi_2 = \phi_3 = 0$.

15. The switching regression model also allows interaction effect, but the switching from one regime to another is not smooth.

16. A nonlinear relation between insider ownership and investment (capital expenditure or R&D expenditure) is estimated by Cho (1998).

17. The equation can easily be modified to allow more than two switching points.

18. We thank the authors for their permission to use the data set in this paper.

Abstract

This paper presents a review of different theoretical approaches to the optimal futures hedge ratios. These approaches are based on minimum variance, mean-variance, expected utility, mean extended-Gini coefficient, semivariance and Value-at-Risk. Various ways of estimating these hedge ratios are also discussed, ranging from simple ordinary least squares to complicated heteroscedastic cointegration methods. Under martingale and joint-normality conditions, different hedge ratios are the same as the minimum variance hedge ratio. Otherwise, the optimal hedge ratios based on the different approaches are in general different and there is no single optimal hedge ratio that is distinctly superior to the remaining ones.

Keywords

Cointegration • Gini coefficient • Hedge ratio • Minimum variance • Semi variance

74.1 Introduction

One of the best uses of derivative securities such as futures contracts is in hedging. In the past, both academicians and practitioners have shown great interest in the issue of hedging with futures. This is quite evident from the large number of articles written in this area.

One of the main theoretical issues in hedging involves the determination of the optimal hedge ratio. However, the optimal hedge ratio depends on the particular objective function to be optimized. Many different objective functions are currently being used. For example, one of the most widely-used hedging strategies is based on the minimization of the variance of the hedged portfolio (e.g., see Johnson, 1960; Ederington, 1979; Myers and Thompson, 1989). This so-called minimum-variance (MV) hedge ratio is simple to understand and estimate. However, the MV hedge ratio completely ignores the expected return of the hedged portfolio. Therefore, this strategy is in general inconsistent with the mean-variance framework unless the individuals are infinitely risk-averse or the futures price follows a pure martingale process (i.e., expected futures price change is zero).

Other strategies that incorporate both the expected return and risk (variance) of the hedged portfolio have been recently proposed (e.g., see Howard and D'Antonio, 1984; Cecchetti et al., 1988; Hsin et al., 1994). These strategies are consistent with the mean-variance framework. However, it can be shown that if the futures price follows a pure martingale process, then the optimal mean-variance hedge ratio will be the same as the MV hedge ratio.

Another aspect of the mean-variance based strategies is that even though they are an improvement over the MV strategy, for them to be consistent with the expected utility maximization principle, either the utility function needs to be quadratic or the returns should be jointly normal. If neither of these assumptions is valid, then the hedge ratio may not be optimal with respect to the expected utility maximization principle. Some researchers have solved this problem by deriving the optimal hedge ratio based on the maximization of the expected utility (e.g., see Cecchetti et al., 1988; Lence, 1995, 1996). However, this approach requires the use of specific utility function and specific return distribution.

Attempts have been made to eliminate these specific assumptions regarding the utility function and return distributions. Some of them involve the minimization of the mean extended-Gini (MEG) coefficient, which is consistent with the concept of stochastic dominance (e.g., see Cheung et al., 1990; Kolb and Okunev, 1992, 1993; Lien and Luo, 1993a; Shalit, 1995; Lien and Shaffer, 1999). Shalit (1995) shows that if the prices are normally distributed, then the MEG-based hedge ratio will be the same as the MV hedge ratio.

Recently, hedge ratios based on the generalized semivariance (GSV) or lower partial moments have been proposed (e.g., see De Jong et al., 1997; Lien and Tse, 1998, 2000; Chen et al., 2001). These hedge ratios are also consistent with the concept of stochastic dominance. Furthermore, these GSV-based hedge ratios have another attractive feature whereby they measure portfolio risk by the GSV, which is consistent with the risk perceived by managers, because of its emphasis on the returns below the target return (see Crum et al., 1981; Lien and Tse, 2000). Lien and Tse (1998) show that if the futures and spot returns are jointly normally distributed and if the futures price follows a pure martingale process, then the minimum-GSV hedge ratio will be equal to the MV hedge ratio. Finally, Hung et al. (2006) has proposed a related hedge ratio that minimizes the Value-at-Risk associated with the hedged portfolio when choosing hedge ratio. This hedge ratio will also be equal to MV hedge ratio if the futures price follows a pure martingale process.

Most of the studies mentioned above (except Lence, 1995, 1996) ignore transaction costs as well as investments in other securities. Lence (1995, 1996) derives the optimal hedge ratio where transaction costs and investments in other

securities are incorporated in the model. Using a CARA utility function, Lence finds that under certain circumstances the optimal hedge ratio is zero; i.e., the optimal hedging strategy is not to hedge at all.

In addition to the use of different objective functions in the derivation of the optimal hedge ratio, previous studies also differ in terms of the dynamic nature of the hedge ratio. For example, some studies assume that the hedge ratio is constant over time. Consequently, these static hedge ratios are estimated using unconditional probability distributions (e.g., see Ederington, 1979; Howard and D'Antonio, 1984; Benet, 1992; Kolb and Okunev, 1992, 1993; Ghosh, 1993). On the other hand, several studies allow the hedge ratio to change over time. In some cases, these dynamic hedge ratios are estimated using conditional distributions associated with models such as ARCH and GARCH (e.g., see Cecchetti et al., 1988; Baillie and Myers, 1991; Kroner and Sultan, 1993; Sephton, 1993a). The GARCH based method has recently been extended by Lee and Yoder (2007) where regime-switching model is used. Alternatively, the hedge ratios can be made dynamic by considering a multi-period model where the hedge ratios are allowed to vary for different periods. This is the method used by Lien and Luo (1993b).

When it comes to estimating the hedge ratios, many different techniques are currently being employed, ranging from simple to complex ones. For example, some of them use such a simple method as the ordinary least squares (OLS) technique (e.g., see Ederington, 1979; Malliaris and Urrutia, 1991; Benet, 1992). However, others use more complex methods such as the conditional heteroscedastic (ARCH or GARCH) method (e.g., see Cecchetti et al., 1988; Baillie and Myers, 1991; Sephton, 1993a), the random coefficient method (e.g., see Grammatikos and Saunders, 1983), the cointegration method (e.g., see Ghosh, 1993; Lien and Luo, 1993b; Chou et al., 1996), or the cointegration-heteroscedastic method (e.g., see Kroner and Sultan, 1993). Recently, Lien and Shrestha (2007) has suggested the use of wavelet analysis to match the data frequency with the hedging horizon. Finally, Lien and Shrestha (2010) also suggests the use of multivariate skew-normal distribution in estimating the minimum variance hedge ratio.

It is quite clear that there are several different ways of deriving and estimating hedge ratios. In the paper we review these different techniques and approaches and examine their relations.

The paper is divided into five sections. In Section 74.2 alternative theories for deriving the optimal hedge ratios are reviewed. Various estimation methods are discussed in Section 74.3. Section 74.4 presents a discussion on the relationship among lengths of hedging horizon, maturity of futures contract, data frequency, and hedging effectiveness. Finally, in Section 74.5 we provide a summary and conclusion.

74.2 Alternative Theories for Deriving the Optimal Hedge Ratio

The basic concept of hedging is to combine investments in the spot market and futures market to form a portfolio that will eliminate (or reduce) fluctuations in its value. Specifically, consider a portfolio consisting of C_s units of a long spot position and C_f units of a short futures position.[1] Let S_t and F_t denote the spot and futures prices at time t, respectively. Since the futures contracts are used to reduce the fluctuations in spot positions, the resulting portfolio is known as the hedged portfolio. The return on the hedged portfolio, R_h, is given by:

$$R_h = \frac{C_s S_t R_s - C_f F_t R_f}{C_s S_t} = R_s - h R_f, \qquad (74.1a)$$

where $h = \frac{C_f F_t}{C_s S_t}$ is the so-called hedge ratio, and $R_s = \frac{S_{t+1} - S_t}{S_t}$ and $R_f = \frac{F_{t+1} - F_t}{F_t}$ are so-called one-period returns on the spot and futures positions, respectively. Sometimes, the hedge ratio is discussed in terms of price changes (profits) instead of returns. In this case the profit on the hedged portfolio, ΔV_H, and the hedge ratio, H, are respectively given by:

$$\Delta V_H = C_s \Delta S_t - C_f \Delta F_t \text{ and } H = \frac{C_f}{C_s} \qquad (74.1b)$$

where $\Delta S_t = S_{t+1} - S_t$ and $\Delta F_t = F_{t+1} - F_t$.

The main objective of hedging is to choose the optimal hedge ratio (either h or H). As mentioned above, the optimal hedge ratio will depend on a particular objective function to be optimized. Furthermore, the hedge ratio can be static or dynamic. In subsections A and B, we will discuss the static hedge ratio and then the dynamic hedge ratio.

It is important to note that in the above setup, the cash position is assumed to be fixed and we only look for the optimum futures position. Most of the hedging literature assumes that the cash position is fixed, a setup that is suitable for financial futures. However, when we are dealing with commodity futures, the initial cash position becomes an important decision variable that is tied to the production decision. One such setup considered by Lence (1995, 1996) will be discussed in subsection C.

74.2.1 Static Case

We consider here that the hedge ratio is static if it remains the same over time. The static hedge ratios reviewed in this paper can be divided into eight categories, as shown in Table 74.1. We will discuss each of them in the paper.

Table 74.1 A list of different static hedge ratios

Hedge ratio	Objective function
Minimum-variance (MV) hedge ratio	Minimize variance of R_h
Optimum mean-variance hedge Ratio	Maximize $E(R_h) - \frac{A}{2} Var(R_h)$
Sharpe hedge ratio	Maximize $\frac{E(R_h) - R_F}{\sqrt{Var(R_h)}}$
Maximum expected utility hedge ratio	Maximize $E[U(W_1)]$
Minimum mean extended-Gini (MEG) coefficient hedge ratio	Minimize $\Gamma_v(R_h v)$
Optimum mean-MEG hedge ratio	Maximize $E[R_h] - \Gamma_v(R_h v)$
Minimum generalized semivariance (GSV) hedge ratio	Minimize $V_{\delta,\alpha}(R_h)$
Maximum mean-GSV hedge ratio	Maximize $E[R_h] - V_{\delta,\alpha}(R_h)$
Minimum VaR hedge ratio over a given time period τ	Minimize $Z_\alpha \sigma_h \sqrt{\tau} - E[R_h]\tau$

Notes
1. R_h = return on the hedged portfolio
$E(R_h)$ = expected return on the hedged portfolio
$Var(R_h)$ = variance of return on the hedged portfolio
σ_h = standard deviation of return on the hedged portfolio
Z_α = negative of left percentile at α for the standard normal distribution
A = risk aversion parameter
R_F = return on the risk-free security
$E(U(W_1))$ = expected utility of end-of-period wealth
$\Gamma_v(R_h v)$ = mean extended-Gini coefficient of R_h
$V_{\delta,\alpha}(R_h)$ = generalized semivariance of R_h
2. With W_1 given by Equation 74.17, the maximum expected utility hedge ratio includes the hedge ratio considered by Lence (1995, 1996)

74.2.1.1 Minimum-Variance Hedge Ratio

The most widely-used static hedge ratio is the minimum-variance (MV) hedge ratio. Johnson (1960) derives this hedge ratio by minimizing the portfolio risk, where the risk is given by the variance of changes in the value of the hedged portfolio as follows:

$$Var(\Delta V_H) = C_s^2 Var(\Delta S) + C_f^2 Var(\Delta F) - 2 C_s C_f Cov \times (\Delta S, \Delta F).$$

The MV hedge ratio, in this case, is given by:

$$H_J^* = \frac{C_f}{C_s} = \frac{Cov(\Delta S, \Delta F)}{Var(\Delta F)}. \qquad (74.2a)$$

Alternatively, if we use definition (74.1a) and use $Var(R_h)$ to represent the portfolio risk, then the MV hedge ratio is obtained by minimizing $Var(R_h)$ which is given by:

$$Var(R_h) = Var(R_s) + h^2 Var(R_f) - 2h Cov(R_s, R_f).$$

In this case, the MV hedge ratio is given by:

$$h_J^* = \frac{Cov(R_s, R_f)}{Var(R_f)} = \rho \frac{\sigma_s}{\sigma_f}, \qquad (74.2b)$$

where ρ is the correlation coefficient between R_s and R_f, and σ_s and σ_f are standard deviations of R_s and R_f, respectively.

The attractive features of the MV hedge ratio are that it is easy to understand and simple to compute. However, in general the MV hedge ratio is not consistent with the mean-variance framework since it ignores the expected return on the hedged portfolio. For the MV hedge ratio to be consistent with the mean-variance framework, either the investors need to be infinitely risk-averse or the expected return on the futures contract needs to be zero.

74.2.1.2 Optimum Mean-Variance Hedge Ratio

Various studies have incorporated both risk and return in the derivation of the hedge ratio. For example, Hsin et al. (1994) derive the optimal hedge ratio that maximizes the following utility function:

$$\underset{C_f}{Max} \ V(E(R_h), \sigma, A) = E(R_h) - 0.5A\sigma_h^2, \qquad (74.3)$$

where A represents the risk aversion parameter. It is clear that this utility function incorporates both risk and return. Therefore, the hedge ratio based on this utility function would be consistent with the mean-variance framework. The optimal number of futures contract and the optimal hedge ratio are respectively given by:

$$h_2 = -\frac{C_f^* F}{C_s S} = -\left[\frac{E(R_f)}{A\sigma_f^2} - \rho \frac{\sigma_s}{\sigma_f}\right]. \qquad (74.4)$$

One problem associated with this type of hedge ratio is that in order to derive the optimum hedge ratio, we need to know the individual's risk aversion parameter. Furthermore, different individuals will choose different optimal hedge ratios, depending on the values of their risk aversion parameter.

Since the MV hedge ratio is easy to understand and simple to compute, it will be interesting and useful to know under what condition the above hedge ratio would be the same as the MV hedge ratio. It can be seen from Equations 74.2b and 74.4 that if $A \to \infty$ or $E(R_f) = 0$, then h_2 would be equal to the MV hedge ratio h_J^*. The first condition is simply a restatement of the infinitely risk-averse individuals. However, the second condition does not impose any condition on the risk-averseness, and this is important. It implies that even if the individuals are not infinitely risk averse, then the MV hedge ratio would be the same as the optimal mean-variance hedge ratio if the expected return on the futures contract is zero (i.e. futures prices follow a simple martingale process). Therefore, if futures prices follow a simple martingale

process, then we do not need to know the risk aversion parameter of the investor to find the optimal hedge ratio.

74.2.1.3 Sharpe Hedge Ratio

Another way of incorporating the portfolio return in the hedging strategy is to use the risk-return tradeoff (Sharpe measure) criteria. Howard and D'Antonio (1984) consider the optimal level of futures contracts by maximizing the ratio of the portfolio's excess return to its volatility:

$$\underset{C_f}{Max} \ \theta = \frac{E(R_h) - R_F}{\sigma_h}, \qquad (74.5)$$

where $\sigma_h^2 = Var(R_h)$ and R_F represents the risk-free interest rate. In this case the optimal number of futures positions, C_f^*, is given by:

$$C_f^* = -C_s \frac{\left(\frac{S}{F}\right)\left(\frac{\sigma_s}{\sigma_f}\right)\left[\frac{\sigma_s}{\sigma_f}\left(\frac{E(R_f)}{E(R_s) - R_F}\right) - \rho\right]}{\left[1 - \frac{\sigma_s}{\sigma_f}\left(\frac{E(R_f)\rho}{E(R_s) - R_F}\right)\right]}. \qquad (74.6)$$

From the optimal futures position, we can obtain the following optimal hedge ratio:

$$h_3 = -\frac{\left(\frac{\sigma_s}{\sigma_f}\right)\left[\frac{\sigma_s}{\sigma_f}\left(\frac{E(R_f)}{E(R_s) - R_F}\right) - \rho\right]}{\left[1 - \frac{\sigma_s}{\sigma_f}\left(\frac{E(R_f)\rho}{E(R_s) - R_F}\right)\right]}. \qquad (74.7)$$

Again, if $E(R_f) = 0$, then h_3 reduces to:

$$h_3 = \left(\frac{\sigma_s}{\sigma_f}\right)\rho, \qquad (74.8)$$

which is the same as the MV hedge ratio h_J^*.

As pointed out by Chen et al. (2001), the Sharpe ratio is a highly non-linear function of the hedge ratio. Therefore, it is possible that Equation 74.7, which is derived by equating the first derivative to zero, may lead to the hedge ratio that would minimize, instead of maximizing, the Sharpe ratio. This would be true if the second derivative of the Sharpe ratio with respect to the hedge ratio is positive instead of negative. Furthermore, it is possible that the optimal hedge ratio may be undefined as in the case encountered by Chen et al. (2001), where the Sharpe ratio monotonically increases with the hedge ratio.

74.2.1.4 Maximum Expected Utility Hedge Ratio

So far we have discussed the hedge ratios that incorporate only risk as well as the ones that incorporate both risk and

return. The methods, which incorporate both the expected return and risk in the derivation of the optimal hedge ratio, are consistent with the mean-variance framework. However, these methods may not be consistent with the expected utility maximization principle unless either the utility function is quadratic or the returns are jointly normally distributed. Therefore, in order to make the hedge ratio consistent with the expected utility maximization principle, we need to derive the hedge ratio that maximizes the expected utility. However, in order to maximize the expected utility we need to assume a specific utility function. For example, Cecchetti et al. (1988) derive the hedge ratio that maximizes the expected utility where the utility function is assumed to be the logarithm of terminal wealth. Specifically, they derive the optimal hedge ratio that maximizes the following expected utility function:

$$\int_{R_s}\int_{R_f} \log\left[1 + R_s - hR_f\right]f\left(R_s, R_f\right)dR_s dR_f,$$

where the density function $f\left(R_s, R_f\right)$ is assumed to be bivariate normal. A third-order linear bivariate ARCH model is used to get the conditional variance and covariance matrix, and a numerical procedure is used to maximize the objective function with respect to the hedge ratio.[2]

74.2.1.5 Minimum Mean Extended-Gini Coefficient Hedge Ratio

This approach of deriving the optimal hedge ratio is consistent with the concept of stochastic dominance and involves the use of the mean extended-Gini (MEG) coefficient. Cheung et al. (1990), Kolb and Okunev (1992), Lien and Luo (1993a), Shalit (1995), and Lien and Shaffer (1999) all consider this approach. It minimizes the MEG coefficient $\Gamma_v(R_h)$ defined as follows:

$$\Gamma_v(R_h) = -vCov\left(R_h, (1 - G(R_h))^{v-1}\right), \qquad (74.9)$$

where G is the cumulative probability distribution and v is the risk aversion parameter. Note that $0 \leq v < 1$ implies risk seekers, $v = 1$ implies risk-neutral investors, and $v > 1$ implies risk-averse investors. Shalit (1995) has shown that if the futures and spot returns are jointly normally distributed, then the minimum-MEG hedge ratio would be the same as the MV hedge ratio.

74.2.1.6 Optimum Mean-MEG Hedge Ratio

Instead of minimizing the MEG coefficient, Kolb and Okunev (1993) alternatively consider maximizing the utility function defined as follows:

$$U(R_h) = E(R_h) - \Gamma_v(R_h). \qquad (74.10)$$

The hedge ratio based on the utility function defined by Equation 74.10 is denoted as the M-MEG hedge ratio. The difference between the MEG and M-MEG hedge ratios is that the MEG hedge ratio ignores the expected return on the hedged portfolio. Again, if the futures price follows a martingale process (i.e., $E(R_f) = 0$), then the MEG hedge ratio would be the same as the M-MEG hedge ratio.

74.2.1.7 Minimum Generalized Semivariance Hedge Ratio

In recent years a new approach for determining the hedge ratio has been suggested (see De Jong et al., 1997; Lien and Tse, 1998, 2000; Chen et al., 2001). This new approach is based on the relationship between the generalized semivariance (GSV) and expected utility as discussed by Fishburn (1977) and Bawa (1978). In this case the optimal hedge ratio is obtained by minimizing the GSV given below:

$$V_{\delta,\alpha}(R_h) = \int_{-\infty}^{\delta} (\delta - R_h)^{\alpha} dG(R_h), \quad \alpha > 0, \qquad (74.11)$$

where $G(R_h)$ is the probability distribution function of the return on the hedged portfolio R_h. The parameters δ and α (which are both real numbers) represent the target return and risk aversion, respectively. The risk is defined in such a way that the investors consider only the returns below the target return (δ) to be risky. It can be shown (see Fishburn, 1977) that $\alpha < 1$ represents a risk-seeking investor and $\alpha > 1$ represents a risk-averse investor.

The GSV, due to its emphasis on the returns below the target return, is consistent with the risk perceived by managers (see Crum et al., 1981; Lien and Tse, 2000). Furthermore, as shown by Fishburn (1977) and Bawa (1978), the GSV is consistent with the concept of stochastic dominance. Lien and Tse (1998) show that the GSV hedge ratio, which is obtained by minimizing the GSV, would be the same as the MV hedge ratio if the futures and spot returns are jointly normally distributed and if the futures price follows a pure martingale process.

74.2.1.8 Optimum Mean-Generalized Semivariance Hedge Ratio

Chen et al. (2001) extend the GSV hedge ratio to a Mean-GSV (M-GSV) hedge ratio by incorporating the mean return in the derivation of the optimal hedge ratio. The M-GSV hedge ratio is obtained by maximizing the following mean-risk utility function, which is similar to the conventional mean-variance based utility function (see Equation 74.3):

$$U(R_h) = E[R_h] - V_{\delta,\alpha}(R_h). \qquad (74.12)$$

This approach to the hedge ratio does not use the risk aversion parameter to multiply the GSV as done in conventional mean-risk models (see Hsin et al., 1994 and Equation 74.3). This is because the risk aversion parameter is already included in the definition of the GSV, $V_{\delta,\alpha}(R_h)$. As before, the M-GSV hedge ratio would be the same as the GSV hedge ratio if the futures price follows a pure martingale process.

74.2.1.9 Minimum Value-at-Risk Hedge Ratio

Hung et al. (2006) suggests a new hedge ratio that minimizes the Value-at-Risk of the hedged portfolio. Specifically, the hedge ratio h is derived by minimizing the following Value-at-Risk of the hedged portfolio over a given time period τ:

$$VaR(R_h) = Z_\alpha \sigma_h \sqrt{\tau} - E[R_h]\tau \qquad (74.13)$$

The resulting optimal hedge ratio, which Hung et al. (2006) refer to as zero-VaR hedge ratio, is given by

$$h^{VaR} = \rho \frac{\sigma_s}{\sigma_f} - E[R_f] \frac{\sigma_s}{\sigma_f} \sqrt{\frac{1 - \rho^2}{Z_\alpha^2 \sigma_f^2 - E[R_f]^2}} \qquad (74.14)$$

It is clear that, if the futures price follows martingale process, the zero-VaR hedge ratio would be the same as the MV hedge ratio.

74.2.2 Dynamic Case

We have up to now examined the situations in which the hedge ratio is fixed at the optimum level and is not revised during the hedging period. However, it could be beneficial to change the hedge ratio over time. One way to allow the hedge ratio to change is by recalculating the hedge ratio based on the current (or conditional) information on the covariance (σ_{sf}) and variance (σ_f^2). This involves calculating the hedge ratio based on conditional information (i.e., $\sigma_{sf}|\Omega_{t-1}$ and $\sigma_f^2|\Omega_{t-1}$) instead of unconditional information. In this case, the MV hedge ratio is given by:

$$h_1|\Omega_{t-1} = -\frac{\sigma_{sf}|\Omega_{t-1}}{\sigma_f^2|\Omega_{t-1}}.$$

The adjustment to the hedge ratio based on new information can be implemented using such conditional models as ARCH and GARCH (to be discussed later) or using the moving window estimation method.

Another way of making the hedge ratio dynamic is by using the regime switching GARCH model (to be discussed later) as suggested by Lee and Yoder (2007). This model assumes two different regimes where each regime is associated with different set of parameters and the probabilities of regime switching must also be estimated when implementing such method. Alternatively, we can allow the hedge ratio to change during the hedging period by considering multi-period models, which is the approach used by Lien and Luo (1993b).

Lien and Luo (1993b) consider hedging with T periods' planning horizon and minimize the variance of the wealth at the end of the planning horizon, W_T. Consider the situation where $C_{s,t}$ is the spot position at the beginning of period t and the corresponding futures position is given by $C_{f,t} = -b_t C_{s,t}$. The wealth at the end of the planning horizon, W_T, is then given by:

$$W_T = W_0 + \sum_{t=0}^{T-1} C_{s,t}[S_{t+1} - S_t - b_t(F_{t+1} - F_t)] \quad (74.15)$$

$$= W_0 + \sum_{t=0}^{T-1} C_{s,t}[\Delta S_{t+1} - b_t \Delta F_{t+1}].$$

The optimal b_t's are given by the following recursive formula:

$$b_t = \frac{Cov(\Delta S_{t+1}, \Delta F_{t+1})}{Var(\Delta F_{t+1})}$$
$$+ \sum_{i=t+1}^{T-1} \left(\frac{C_{s,i}}{C_{s,t}}\right) \frac{Cov(\Delta F_{t+1}, \Delta S_{i+1} + b_i \Delta F_{t+i})}{Var(\Delta F_{t+1})}. \quad (74.16)$$

It is clear from Equation 74.16 that the optimal hedge ratio b_t will change over time. The multi-period hedge ratio will differ from the single-period hedge ratio due to the second term on the right-hand side of Equation 74.16. However, it is interesting to note that the multi-period hedge ratio would be different from the single-period one if the changes in current futures prices are correlated with the changes in future futures prices or with the changes in future spot prices.

74.2.3 Case with Production and Alternative Investment Opportunities

All the models considered in subsections A and B assume that the spot position is fixed or predetermined, and thus production is ignored. As mentioned earlier, such an assumption may be appropriate for financial futures. However, when we consider commodity futures, production should be considered in which case the spot position

becomes one of the decision variables. In an important paper, Lence (1995) extends the model with a fixed or predetermined spot position to a model where production is included. In his model Lence (1995) also incorporates the possibility of investing in a risk-free asset and other risky assets, borrowing, as well as transaction costs. We will briefly discuss the model considered by Lence (1995) below.

Lence (1995) considers a decision maker whose utility is a function of terminal wealth $U(W_1)$, such that $U' > 0$ and $U'' < 0$. At the decision date ($t = 0$)), the decision maker will engage in the production of Q commodity units for sale at terminal date ($t = 1$) at the random cash price P_1. At the decision date, the decision maker can lend L dollars at the -risk-free lending rate ($R_L - 1$) and borrow B dollars at the borrowing rate ($R_B - 1$), invest I dollars in a different activity that yields a random rate of return ($R_I - 1$) and sell X futures at futures price F_0. The transaction cost for the futures trade is f dollars per unit of the commodity traded to be paid at the terminal date. The terminal wealth (W_1) is therefore given by:

$$W_1 = W_0 R = P_1 Q + (F_0 - F_1)X - f|X| - R_B B + R_L L + R_I I, \tag{74.17}$$

where R is the return on the diversified portfolio. The decision maker will maximize the expected utility subject to the following restrictions:

$$W_0 + B \geq v(Q)Q + L + I, \ 0 \leq B \leq k_B v(Q)Q, \ k_B \geq 0,$$

$$L \geq k_L F_0 |X|, \ k_L \geq 0, I \geq 0,$$

where $v(Q)$ is the average cost function, k_B is the maximum amount (expressed as a proportion of his initial wealth) that the agent can borrow, and k_L is the safety margin for the futures contract.

Using this framework, Lence (1995) introduces two opportunity costs: opportunity cost of alternative (sub-optimal) investment (c_{alt}) and opportunity cost of estimation risk (e^{Bayes}).[3] Let R_{opt} be the return of the expected-utility maximizing strategy and let R_{alt} be the return on a particular alternative (sub-optimal) investment strategy. The opportunity cost of alternative investment strategy c_{alt} is then given by:

$$E[U(W_0 R_{opt})] = E[U(W_0 R_{alt} + c_{alt})]. \tag{74.18}$$

In other words, c_{alt} is the minimum certain net return required by the agent to invest in the alternative (sub-optimal hedging) strategy rather than in the optimum strategy. Using

the CARA utility function and some simulation results, Lence (1995) finds that the expected-utility maximizing hedge ratios are substantially different from the minimum-variance hedge ratios. He also shows that under certain conditions, the optimal hedge ratio is zero; i.e., the optimal strategy is not to hedge at all.

Similarly, the opportunity cost of the estimation risk (e^{Bayes}) is defined as follows:

$$E_\rho \left[E \left(U \left\{ W_0 \left[R_{opt}(\rho) - e_\rho^{Bayes} \right] \right\} \right) \right]$$
$$= E_\rho \left[E \left(U \left(W_0 R_{opt}^{Bayes} \right) \right) \right], \tag{74.19}$$

where $R_{opt}(\rho)$ is the expected-utility maximizing return where the agent knows with certainty the value of the correlation between the futures and spot prices (ρ), R_{opt}^{Bayes} is the expected-utility maximizing return where the agent only knows the distribution of the correlation ρ, and $E_\rho[.]$ is the expectation with respect to ρ. Using simulation results, Lence (1995) finds that the opportunity cost of the estimation risk is negligible and thus the value of the use of sophisticated estimation methods is negligible.

74.3 Alternative Methods for Estimating the Optimal Hedge Ratio

In Section 74.2 we discussed different approaches to deriving the optimum hedge ratios. However, in order to apply these optimum hedge ratios in practice, we need to estimate these hedge ratios. There are various ways of estimating them. In this section we briefly discuss these estimation methods.

74.3.1 Estimation of the Minimum-Variance (MV) Hedge Ratio

74.3.1.1 OLS Method
The conventional approach to estimating the MV hedge ratio involves the regression of the changes in spot prices on the changes in futures price using the OLS technique (e.g., see Junkus and Lee, 1985). Specifically, the regression equation can be written as:

$$\Delta S_t = a_0 + a_1 \Delta F_t + e_t, \tag{74.20}$$

where the estimate of the MV hedge ratio, H_j, is given by a_1. The OLS technique is quite robust and simple to use. However, for the OLS technique to be valid and efficient, assumptions associated with the OLS regression must be satisfied. One case where the assumptions are not completely

satisfied is that the error term in the regression is heteroscedastic. This situation will be discussed later.

Another problem with the OLS method, as pointed out by Myers and Thompson (1989), is the fact that it uses unconditional sample moments instead of conditional sample moments, which use currently available information. They suggest the use of the conditional covariance and conditional variance in Equation 74.2a. In this case, the conditional version of the optimal hedge ratio (Equation 74.2a) will take the following form:

$$H_J^* = \frac{C_f}{C_s} = \frac{Cov(\Delta S, \Delta F)|\Omega_{t-1}}{Var(\Delta F)|\Omega_{t-1}}. \qquad (74.2a^*)$$

Suppose that the current information (Ω_{t-1}) includes a vector of variables (X_{t-1}) and the spot and futures price changes are generated by the following equilibrium model:

$$\Delta S_t = X_{t-1}\alpha + u_t,$$

$$\Delta F_t = X_{t-1}\beta + v_t.$$

In this case the maximum likelihood estimator of the MV hedge ratio is given by (see Myers and Thompson, 1989):

$$\hat{h}|X_{t-1} = \frac{\hat{\sigma}_{uv}}{\hat{\sigma}_v^2}, \qquad (74.21)$$

where $\hat{\sigma}_{uv}$ is the sample covariance between the residuals u_t and v_t, and $\hat{\sigma}_v^2$ is the sample variance of the residual v_t. In general, the OLS estimator obtained from Equation 74.20 would be different from the one given by Equation 74.21. For the two estimators to be the same, the spot and futures prices must be generated by the following model:

$$\Delta S_t = \alpha_0 + u_t, \ \Delta F_t = \beta_0 + v_t.$$

In other words, if the spot and futures prices follow a random walk, then with or without drift, the two estimators will be the same. Otherwise, the hedge ratio estimated from the OLS regression (74.18) will not be optimal.

74.3.1.2 Multivariate Skew-Normal Distribution Method

An alternative way of estimating the MV hedge ratio involves the assumption that the spot price and futures price follows a multivariate skew-normal distribution as suggested by Lien and Shrestha (2010). The estimate of covariance matrix under skew-normal distribution can be different from the estimate of covariance matrix under the usual normal distribution resulting in different estimates of MV hedge ratio. Let Y be a k-dimensional random vector.

Then Y is said to have skew-normal distribution if its probability density function is given as follows:

$$f_Y(y) = 2\varphi_k(y, \Omega_Y)\Phi(\alpha^t y) \qquad (74.22)$$

where α is a k-dimensional column vector, $\varphi_k(y, \Omega_Y)$ is the probability density function of a k-dimensional standard normal random variable with zero mean and correlation matrix Ω_Y and $\Phi(\alpha^t y)$ is the probability distribution function of a one-dimensional standard normal random variable evaluated at $\alpha^t y$.

74.3.1.3 ARCH and GARCH Methods

Ever since the development of ARCH and GARCH models, the OLS method of estimating the hedge ratio has been generalized to take into account the heteroscedastic nature of the error term in Equation 74.20. In this case, rather than using the unconditional sample variance and covariance, the conditional variance and covariance from the GARCH model are used in the estimation of the hedge ratio. As mentioned above, such a technique allows an update of the hedge ratio over the hedging period.

Consider the following bivariate GARCH model (see Cecchetti et al., 1988; Baillie and Myers, 1991):

$$\begin{bmatrix} \Delta S_t \\ \Delta F_t \end{bmatrix} = \begin{bmatrix} \mu_1 \\ \mu_2 \end{bmatrix} + \begin{bmatrix} e_{1t} \\ e_{2t} \end{bmatrix} \ \Leftrightarrow \ \Delta Y_t = \mu + e_t,$$

$$e_t|\Omega_{t-1} \sim N(0, H_t), \quad H_t = \begin{bmatrix} H_{11,t} & H_{12,t} \\ H_{12,t} & H_{22,t} \end{bmatrix},$$

$$vec(H_t) = C + A\,vec\left(e_{t-1}e'_{t-1}\right) + B\,vec(H_{t-1}).$$

The conditional MV hedge ratio at time t is given by $h_{t-1} = H_{12,t}/H_{22,t}$. This model allows the hedge ratio to change over time, resulting in a series of hedge ratios instead of a single hedge ratio for the entire hedging horizon.

The model can be extended to include more than one type of cash and futures contracts (see Sephton, 1993a). For example, consider a portfolio that consists of spot wheat ($S_{1,t}$), spot canola (S_{2t}), wheat futures (F_{1t}) and canola futures (F_{2t}). We then have the following multi-variate GARCH model:

$$\begin{bmatrix} \Delta S_{1t} \\ \Delta S_{2t} \\ \Delta F_{1t} \\ \Delta F_{2t} \end{bmatrix} = \begin{bmatrix} \mu_1 \\ \mu_2 \\ \mu_3 \\ \mu_4 \end{bmatrix} + \begin{bmatrix} e_{1t} \\ e_{2t} \\ e_{3t} \\ e_{4t} \end{bmatrix} \ \Leftrightarrow \ \Delta Y_t = \mu + e_t,$$

$$e_t|\Omega_{t-1} \sim N(0, H_t).$$

The MV hedge ratio can be estimated using a similar technique as described above. For example, the conditional MV hedge ratio is given by the conditional covariance between the spot and futures price changes divided by the conditional variance of the futures price change.

74.3.1.4 Regime-Switching GARCH Model

The GARCH model discussed above can be further extended by allowing regime switching as suggested by Lee and Yoder (2007). Under this model, the data generating process can be in one of two states or regime denoted by state variable $s_t = \{1, 2\}$, which is assumed to follow a first-order Markov process. The state transition probabilities are assumed to follow a logistic distribution where the transition probabilities are given by

$$\Pr(s_t = 1 | s_{t-1} = 1) = \frac{e^{p_0}}{1 + e^{p_0}} \quad \& \quad \Pr(s_t = 2 | s_{t-1} = 2)$$
$$= \frac{e^{q_0}}{1 + e^{q_0}}.$$

The conditional covariance matrix is given by

$$H_{t,s_t} = \begin{bmatrix} h_{1,t,s_t} & 0 \\ 0 & h_{2,t,s_t} \end{bmatrix} \begin{bmatrix} 1 & \rho_{t,s_t} \\ \rho_{t,s_t} & 1 \end{bmatrix} \begin{bmatrix} h_{1,t,s_t} & 0 \\ 0 & h_{2,t,s_t} \end{bmatrix}$$

where

$$h_{1,t,s_t}^2 = \gamma_{1,s_t} + \alpha_{1,s_t} e_{1.t-1}^2 + \beta_{1,s_t} h_{1,t-1}^2$$

$$h_{2,t,s_t}^2 = \gamma_{2,s_t} + \alpha_{2,s_t} e_{2.t-1}^2 + \beta_{2,s_t} h_{2,t-1}^2$$

$$\rho_{t,s_t} = \left(1 - \theta_{1,s_t} - \theta_{2,s_t}\right)\rho + \theta_{1,s_t}\rho_{t-1} + \theta_{2,s_t}\phi_{t-1}$$

$$\varphi_{t-1} = \frac{\sum\limits_{j=1}^{2} \varepsilon_{1,t-j}\varepsilon_{2,t-j}}{\sqrt{\left(\sum\limits_{j=1}^{2} \varepsilon_{1,t-j}^2\right)\left(\sum\limits_{j=1}^{2} \varepsilon_{2,t-j}^2\right)}}, \quad \varepsilon_{i,t} = \frac{e_{i,t}}{h_{it}}, \quad \theta_1, \theta_2$$

$$\geq 0 \ \& \ \theta_1 + \theta_2 \leq 1$$

Once the conditional covariance matrix is estimated, the time varying conditional MV hedge ratio is given by the ratio of the covariance between the spot and futures returns to the variance of the futures return.

74.3.1.5 Random Coefficient Method

There is another way to deal with heteroscedasticity. This involves use of the random coefficient model as suggested by Grammatikos and Saunders (1983). This model employs the following variation of Equation 74.20:

$$\Delta S_t = \beta_0 + \beta_t \Delta F_t + e_t, \qquad (74.23)$$

where the hedge ratio $\beta_t = \bar{\beta} + v_t$ is assumed to be random. This random coefficient model can, in some cases, improve the effectiveness of hedging strategy. However, this technique does not allow for the update of the hedge ratio over time even though the correction for the randomness can be made in the estimation of the hedge ratio.

74.3.1.6 Cointegration and Error Correction Method

The techniques described so far do not take into consideration the possibility that spot price and futures price series could be non-stationary. If these series have unit roots, then this will raise a different issue. If the two series are cointegrated as defined by Engle and Granger (1987), then the regression Equation 74.20 will be mis-specified and an error-correction term must be included in the equation. Since the arbitrage condition ties the spot and futures prices, they cannot drift far apart in the long run. Therefore, if both series follow a random walk, then we expect the two series to be cointegrated in which case we need to estimate the error correction model. This calls for the use of the cointegration analysis.

The cointegration analysis involves two steps. First, each series must be tested for a unit root (e.g., see Dickey and Fuller, 1981; Phillips and Perron, 1988). Second, if both series are found to have a single unit root, then the cointegration test must be performed (e.g., see Engle and Granger, 1987; Johansen and Juselius, 1990; Osterwald-Lenum, 1992).

If the spot price and futures price series are found to be cointegrated, then the hedge ratio can be estimated in two steps (see Ghosh, 1993; Chou et al., 1996). The first step involves the estimation of the following cointegrating regression:

$$S_t = a + bF_t + u_t. \qquad (74.24)$$

The second step involves the estimation of the following error correction model:

$$\Delta S_t = \rho u_{t-1} + \beta \Delta F_t + \sum_{i=1}^{m} \delta_i \Delta F_{t-i} + \sum_{j=1}^{n} \theta_i \Delta S_{t-j} + e_j,$$
$$(74.25)$$

where u_t is the residual series from the cointegrating regression. The estimate of the hedge ratio is given by the estimate of β. Some researchers (e.g., see Lien and Luo, 1993b) assume that the long-run cointegrating relationship is $(S_t - F_t)$, and estimate the following error correction model:

$$\Delta S_t = \rho(S_{t-1} - F_{t-1}) + \beta \Delta F_t + \sum_{i=1}^{m} \delta_i \Delta F_{t-i} + \sum_{j=1}^{n} \theta_i \Delta S_{t-j} + e_j.$$
$$(74.26)$$

Alternatively, Chou et al. (1996) suggest the estimation of the error correction model as follows:

$$\Delta S_t = \alpha \hat{u}_{t-1} + \beta \Delta F_t + \sum_{i=1}^{m} \delta_i \Delta F_{t-i} + \sum_{j=1}^{n} \theta_i \Delta S_{t-j} + e_j, \tag{74.27}$$

where $\hat{u}_{t-1} = S_{t-1} - (a + bF_{t-1})$; i.e., the series $\hat{u}_t$ is the estimated residual series from Equation 74.24. The hedge ratio is given by β in Equation 74.26.

Kroner and Sultan (1993) combine the error-correction model with the GARCH model considered by Cecchetti et al. (1988) and Baillie and Myers (1991) in order to estimate the optimum hedge ratio. Specifically, they use the following model:

$$\begin{bmatrix} \Delta\log_e(S_t) \\ \Delta\log_e(F_t) \end{bmatrix} = \begin{bmatrix} \mu_1 \\ \mu_2 \end{bmatrix} + \begin{bmatrix} \alpha_s(\log_e(S_{t-1}) - \log_e(F_{t-1})) \\ \alpha_f(\log_e(S_{t-1}) - \log_e(F_{t-1})) \end{bmatrix}$$
$$+ \begin{bmatrix} e_{1t} \\ e_{2t} \end{bmatrix},$$
$$\tag{74.28}$$

where the error processes follow a GARCH process. As before, the hedge ratio at time $(t-1)$ is given by $h_{t-1} = H_{12,t}/H_{22,t}$.

74.3.2 Estimation of the Optimum Mean-Variance and Sharpe Hedge Ratios

The optimum mean-variance and Sharpe hedge ratios are given by Equations 74.4 and 74.7 respectively. These hedge ratios can be estimated simply by replacing the theoretical moments by their sample moments. For example, the expected returns can be replaced by sample average returns, the standard deviations can be replaced by the sample standard deviations, and the correlation can be replaced by sample correlation.

74.3.3 Estimation of the Maximum Expected Utility Hedge Ratio

The maximum expected utility hedge ratio involves the maximization of the expected utility. This requires the estimation of distributions of the changes in spot and futures prices. Once the distributions are estimated, one needs to use a numerical technique to get the optimum hedge ratio. One

such method is described in Cecchetti et al. (1988) where an ARCH model is used to estimate the required distributions.

74.3.4 Estimation of Mean Extended-Gini (MEG) Coefficient Based Hedge Ratios

The MEG hedge ratio involves the minimization of the following MEG coefficient:

$$\Gamma_v(R_h) = -vCov\left(R_h, (1 - G(R_h))^{v-1}\right).$$

In order to estimate the MEG coefficient, we need to estimate the cumulative probability density function $G(R_h)$. The cumulative probability density function is usually estimated by ranking the observed return on the hedged portfolio. A detailed description of the process can be found in Kolb and Okunev (1992), and we briefly describe the process here.

The cumulative probability distribution is estimated by using the rank as follows:

$$G(R_{h,i}) = \frac{Rank(R_{h,i})}{N},$$

where N is the sample size. Once we have the series for the probability distribution function, the MEG is estimated by replacing the theoretical covariance by the sample covariance as follows:

$$\Gamma_v^{sample}(R_h) = -\frac{v}{N} \sum_{i=1}^{N} (R_{h,i} - \bar{R}_h)\left((1 - G(R_{h,i}))^{v-1} - \Theta\right), \tag{74.29}$$

where

$$\bar{R}_h = \frac{1}{N} \sum_{i=1}^{N} R_{h,i} \quad \text{and} \quad \Theta = \frac{1}{N} \sum_{i=1}^{N} (1 - G(R_{h,i}))^{v-1}.$$

The optimal hedge ratio is now given by the hedge ratio that minimizes the estimated MEG. Since there is no analytical solution, the numerical method needs to be applied in order to get the optimal hedge ratio. This method is sometimes referred to as the empirical distribution method.

Alternatively, the instrumental variable (IV) method suggested by Shalit (1995) can be used to find the MEG hedge ratio. Shalit's method provides the following analytical solution for the MEG hedge ratio:

$$h^{IV} = \frac{Cov\left(S_{t+1}, [1 - G(F_{t+1})]^{v-1}\right)}{Cov\left(F_{t+1}, [1 - G(F_{t+1})]^{v-1}\right)}.$$

It is important to note that for the IV method to be valid, the cumulative distribution function of the terminal wealth (W_{t+1}) should be similar to the cumulative distribution of the futures price (F_{t+1}); i.e., $G(W_{t+1}) = G(F_{t+1})$. Lien and Shaffer (1999) find that the IV-based hedge ratio (h^{IV}) is significantly different from the minimum MEG hedge ratio.

Lien and Luo (1993a) suggest an alternative method of estimating the MEG hedge ratio. This method involves the estimation of the cumulative distribution function using a non-parametric kernel function instead of using a rank function as suggested above.

Regarding the estimation of the M-MEG hedge ratio, one can follow either the empirical distribution method or the non-parametric kernel method to estimate the MEG coefficient. A numerical method can then be used to estimate the hedge ratio that maximizes the objective function given by Equation 74.10.

74.3.5 Estimation of Generalized Semivariance (GSV) Based Hedge Ratios

The GSV can be estimated from the sample by using the following sample counterpart:

$$V_{\delta,\alpha}^{sample}(R_h) = \frac{1}{N} \sum_{i=1}^{N} \left(\delta - R_{h,i}\right)^{\alpha} U\left(\delta - R_{h,i}\right), \quad (74.30)$$

where

$$U\left(\delta - R_{h,i}\right) = \begin{cases} 1 \text{ for } \delta \geq R_{h,i} \\ 0 \text{ for } \delta < R_{h,i} \end{cases}.$$

Similar to the MEG technique, the optimal GSV hedge ratio can be estimated by choosing the hedge ratio that minimizes the sample GSV, $V_{\delta,\alpha}^{sample}(R_h)$. Numerical methods can be used to search for the optimum hedge ratio. Similarly, the M-GSV hedge ratio can be obtained by minimizing the -mean-risk function given by Equation 74.12, where the expected return on the hedged portfolio is replaced by the sample average return and the GSV is replaced by the sample GSV.

One can instead use the kernel density estimation method suggested by Lien and Tse (2000) to estimate the GSV, and numerical techniques can be used to find the optimum GSV

hedge ratio. Instead of using the kernel method, one can also employ the conditional heteroscedastic model to estimate the density function. This is the method used by Lien and Tse (1998).

74.4 Hedging Horizon, Maturity of Futures Contract, Data Frequency, and Hedging Effectiveness

In this section we discuss the relationship among the length of hedging horizon (hedging period), maturity of futures contracts, data frequency (e.g., daily, weekly, monthly, or quarterly), and hedging effectiveness.

Since there are many futures contracts (with different maturities) that can be used in hedging, the question is whether the minimum-variance (MV) hedge ratio depends on the time to maturity of the futures contract being used for hedging. Lee et al. (1987) find that the MV hedge ratio increases as the maturity is approached. This means that if we use the nearest to maturity futures contracts to hedge, then the MV hedge ratio will be larger compared to the one obtained using futures contracts with a longer maturity.

Aside from using futures contracts with different maturities, we can estimate the MV hedge ratio using data with different frequencies. For example, the data used in the estimation of the optimum hedge ratio can be daily, weekly, monthly, or quarterly. At the same time, the hedging horizon could be from a few hours to more than a month. The question is whether a relationship exists between the data frequency used and the length of the hedging horizon.

Malliaris and Urrutia (1991) and Benet (1992) utilize Equation 74.20 and weekly data to estimate the optimal hedge ratio. According to Malliaris and Urrutia (1991), the *ex ante* hedging is more effective when the hedging horizon is 1 week compared to a hedging horizon of 4 weeks. Benet (1992) finds that a shorter hedging horizon (4-weeks) is more effective (in *ex ante* test) compared to a longer hedging horizon (8-weeks and 12-weeks). These empirical results seem to be consistent with the argument that when estimating the MV hedge ratio, the hedging horizon's length must match the data frequency being used.

There is a potential problem associated with matching the length of the hedging horizon and the data frequency. For example, consider the case where the hedging horizon is 3 months (one quarter). In this case we need to use quarterly data to match the length of the hedging horizon. In other words, when estimating Equation 74.20 we must employ quarterly changes in spot and futures prices. Therefore, if we have 5 years' worth of data, then we will have 19 non-overlapping price changes, resulting in a sample size of

19. However, if the hedging horizon is 1 week, instead of 3 months, then we will end up with approximately 260 non-overlapping price changes (sample size of 260) for the same 5 years' worth of data. Therefore, the matching method is associated with a reduction in sample size for a longer hedging horizon.

One way to get around this problem is to use overlapping price changes. For example, Geppert (1995) utilizes k-period differencing for a k-period hedging horizon in estimating the regression-based MV hedge ratio. Since Geppert (1995) uses approximately 13 months of data for estimating the hedge ratio, he employs overlapping differencing in order to eliminate the reduction in sample size caused by differencing. However, this will lead to correlated observations instead of independent observations and will require the use of a regression with autocorrelated errors in the estimation of the hedge ratio.

In order to eliminate the autocorrelated errors problem, Geppert (1995) suggests a method based on cointegration and unit-root processes. We will briefly describe his method. Suppose that the spot and futures prices, which are both unit-root processes, are cointegrated. In this case the futures and spot prices can be described by the following processes (see Stock and Watson, 1988; Hylleberg and Mizon, 1989):

$$S_t = A_1 P_t + A_2 \tau_t, \tag{74.31a}$$

$$F_t = B_1 P_t + B_2 \tau_t, \tag{74.31b}$$

$$P_t = P_{t-1} + w_t, \tag{74.31c}$$

$$\tau_t = \alpha_1 \tau_{t-1} + v_t, \quad 0 \le |\alpha_1| < 1, \tag{74.31d}$$

where P_t and τ_t are permanent and transitory factors that drive the spot and futures prices and w_t and v_t are white noise processes. Note that P_t follows a pure random walk process and τ_t follows a stationary process. The MV hedge ratio for a k-period hedging horizon is then given by (see Geppert, 1995):

$$H_J^* = \frac{A_1 B_1 k \sigma_w^2 + 2 A_2 B_2 \left(\frac{(1-\alpha^k)}{1-\alpha^2} \right) \sigma_v^2}{B_1^2 k \sigma_w^2 + 2 B_2^2 \left(\frac{(1-\alpha^k)}{1-\alpha^2} \right) \sigma_v^2}. \tag{74.32}$$

One advantage of using Equation 74.32 instead of a regression with non-overlapping price changes is that it avoids the problem of a reduction in sample size associated with non-overlapping differencing.

An alternative way of matching the data frequency with the hedging horizon is by using the wavelet to decompose the time series into different frequencies as suggested by Lien and Shrestha (2007). The decomposition can be done without the loss of sample size (see Lien and Shrestha, 2007 for detail). For example, the daily spot and future returns series can be decomposed using the maximal overlap discrete wavelet transform (MODWT) as follows:

$$R_{s,t} = B_{J,t}^s + D_{J,t}^s + D_{J-1,t}^s + \cdots + D_{1,t}^s$$

$$R_{f,t} = B_{J,t}^f + D_{J,t}^f + D_{J-1,t}^f + \cdots + D_{1,t}^f$$

where $D_{j,t}^s$ and $D_{j,t}^f$ are the spot and futures returns series with changes on the time scale of length 2^{j-1} days respectively.[4] Similarly, $B_{J,t}^s$ and $B_{J,t}^2$ represents spot and futures returns series corresponding to time scale of 2^J days and longer. Now, we can run the following regression to find the hedge ratio corresponding to hedging horizon equal to 2^{j-1} days:

$$D_{j,t}^s = \theta_{j,0} + \theta_{j,1} D_{j,t}^f + e_j \tag{74.33}$$

where the estimate of the hedge ratio is given by the estimate of $\theta_{j,1}$.

74.5 Summary and Conclusions

In this paper we have reviewed various approaches to deriving the optimal hedge ratio, as summarized in Appendix A. These approaches can be divided into the mean-variance based approach, the expected utility maximizing approach, the mean extended-Gini coefficient-based approach, and the generalized semivariance-based approach. All these approaches will lead to the same hedge ratio as the conventional minimum-variance (MV) hedge ratio if the futures price follows a pure martingale process and if the futures and spot prices are jointly normal. However, if these conditions do not hold, then the hedge ratios based on the various approaches will be different.

The MV hedge ratio is the most understood and most widely-used hedge ratio. Since the statistical properties of the MV hedge ratio are well known, statistical hypothesis testing can be performed with the MV hedge ratio. For example, we can test whether the optimal MV hedge ratio is the same as the naïve hedge ratio. Since the MV hedge ratio ignores the expected return, it will not be consistent with the mean-variance analysis unless the futures price follows a pure martingale process. Furthermore, if the martingale and normality condition do not hold, then the MV hedge ratio will not be consistent with the expected utility

maximization principle. Following the MV hedge ratio is the mean-variance hedge ratio. Even if this hedge ratio incorporates the expected return in the derivation of the optimal hedge ratio, it will not be consistent with the expected maximization principle unless either the normality condition holds or the utility function is quadratic.

In order to make the hedge ratio consistent with the expected utility maximization principle, we can derive the optimal hedge ratio by maximizing the expected utility. However, to implement such approach, we need to assume a specific utility function and we need to make an assumption regarding the return distribution. Therefore, different utility functions will lead to different optimal hedge ratios. Furthermore, analytic solutions for such hedge ratios are not known and numerical methods need to be applied.

New approaches have recently been suggested in deriving optimal hedge ratios. These include the mean-Gini coefficient-based hedge ratio, semivariance-based hedge ratios and Value-at-Risk based hedge ratios. These hedge ratios are consistent with the second-order stochastic dominance principle. Therefore, such hedge ratios are very general in the sense that they are consistent with the expected utility maximization principle and make very few assumptions on the utility function. The only requirement is that the marginal utility be positive and the second derivative of the utility function be negative. However, both of these hedge ratios do not lead to a unique hedge ratio. For example, the mean-Gini coefficient-based hedge ratio depends on the risk aversion parameter (v) and the semivariance-based hedge ratio depends on the risk aversion parameter (α) and target return (δ). It is important to note, however, that the semivariance-based hedge ratio has some appeal in the sense that the semivariance as a measure of risk is consistent with the risk perceived by individuals. The same argument can be applied to Value-at-Risk based hedge ratio.

So far as the derivation of the optimal hedge ratio is concerned, almost all of the derivations do not incorporate transaction costs. Furthermore, these derivations do not allow investments in securities other than the spot and corresponding futures contracts. As shown by Lence (1995), once we relax these conventional assumptions, the resulting optimal hedge ratio can be quite different from the ones obtained under the conventional assumptions. Lence's (1995) results are based on a specific utility function and some other assumption regarding the return distributions. It remains to be seen if such results hold for the mean extended-Gini coefficient-based as well as semivariance-based hedge ratios.

In this paper we have also reviewed various ways of estimating the optimum hedge ratio, as summarized in Appendix B. As far as the estimation of the conventional MV hedge ratio is concerned, there are a large number of methods that have been proposed in the literature. These methods range from a simple regression method to complex cointegrated heteroscedastic methods with regime-switching, and some of the estimation methods include a kernel density function method as well as an empirical distribution method. Except for many of mean-variance based hedge ratios, the estimation involves the use of a numerical technique. This has to do with the fact that most of the optimal hedge ratio formulae do not have a closed-form analytic expression. Again, it is important to mention that based on his specific model, Lence (1995) finds that the value of complicated and sophisticated estimation methods is negligible. It remains to be seen if such a result holds for the mean extended-Gini coefficient-based as well as semivariance-based hedge ratios.

In this paper, we have also discussed about the relationship between the optimal MV hedge ratio and the hedging horizon. We feel that this relationship has not been fully explored and can be further developed in the future. For example, we would like to know if the optimal hedge ratio approaches the naïve hedge ratio when the hedging horizon becomes longer.

The main thing we learn from this review is that if the futures price follows a pure martingale process and if the returns are jointly normally distributed, then all different hedge ratios are the same as the conventional MV hedge ratio, which is simple to compute and easy to understand. However, if these two conditions do not hold, then there are many optimal hedge ratios (depending on which objective function one is trying to optimize) and there is no single optimal hedge ratio that is distinctly superior to the remaining ones. Therefore, further research needs to be done to unify these different approaches to the hedge ratio.

For those who are interested in research in this area, we would like to finally point out that one requires a good understanding of financial economic theories and econometric methodologies. In addition, a good background in data analysis and computer programming would also be helpful.

Notes

1. Without loss of generality, we assume that the size of the futures contract is one.
2. Lence (1995) also derives the hedge ratio based on the expected utility. We will discuss it later in subsection C.
3. Our discussion of the opportunity costs is very brief. We would like to refer interested readers to Lence (1995) for a detailed discussion. We would also like to point to the fact that production can be allowed to be random as is done in Lence (1996).
4. For example, $D_{1,t}^s$ represents daily time scale and $D_{4,t}^s$ represents 8-day time scale.

Appendix A: Theoretical Models

References	Return definition and objective function	Summary
Johnson (1960)	Ret$_1$ O$_1$	The paper derives the minimum-variance hedge ratio. The hedging effectiveness is defined as E$_1$, but no empirical analysis is done
Hsin et al. (1994)	Ret$_2$ O$_2$	The paper derives the utility function-based hedge ratio. A new measure of hedging effectiveness E$_2$ based on a certainty equivalent is proposed. The new measure of hedging effectiveness is used to compare the effectiveness of futures and options as hedging instruments
Howard and D'Antonio (1984)	Ret$_2$ O$_3$	The paper derives the optimal hedge ratio based on maximizing the Sharpe ratio. The proposed hedging effectiveness E$_3$ is based on the Sharpe ratio
Cecchetti et al. (1988)	Ret$_2$ O$_4$	The paper derives the optimal hedge ratio that maximizes the expected utility function: $\int_{R_s} \int_{R_f} \log\left[1 + R_s(t) - h(t)R_f(t)\right] f_t\left(R_s, R_f\right) dR_s dR_f$, where the density function is assumed to be bivariate normal. A third-order linear bivariate ARCH model is used to get the conditional variance and covariance matrix. A numerical procedure is used to maximize the objective function with respect to hedge ratio. Due to ARCH, the hedge ratio changes over time. The paper uses certainty equivalent (E$_2$) to measure the hedging effectiveness
Cheung et al. (1990)	Ret$_2$ O$_5$	The paper uses mean-Gini ($v = 2$, not mean extended-Gini coefficient) and mean-variance approaches to analyze the effectiveness of options and futures as hedging instruments
Kolb and Okunev (1992)	Ret$_2$ O$_5$	The paper uses mean extended-Gini coefficient in the derivation of the optimal hedge ratio. Therefore, it can be considered as a generalization of the mean-Gini coefficient method used by Cheung et al. (1990)
Kolb and Okunev (1993)	Ret$_2$ O$_6$	The paper defines the objective function as O$_6$, but in terms of wealth (W) $U(W) = E[W] - \Gamma_v(W)$ and compares with the quadratic utility function $U(W) = E[W] - m\sigma^2$. The paper plots the EMG efficient frontier in W and $\Gamma_v(W)$ space for various values of risk aversion parameters (v)
Lien and Luo (1993b)	Ret$_1$ O$_9$	The paper derives the multi-period hedge ratios where the hedge ratios are allowed to change over the hedging period. The method suggested in the paper still falls under the minimum-variance hedge ratio
Lence (1995)	O$_4$	This paper derives the expected utility maximizing hedge ratio where the terminal wealth depends on the return on a diversified portfolio that consists of the production of a spot

		commodity, investment in a risk-free asset, investment in a risky asset, as well as borrowing. It also incorporates the transaction costs
De Jong et al. (1997)	Ret$_2$ O$_7$ (also uses O$_1$ and O$_3$)	The paper derives the optimal hedge ratio that minimizes the generalized semivariance (GSV). The paper compares the GSV hedge ratio with the minimum-variance (MV) hedge ratio as well as the Sharpe hedge ratio. The paper uses E$_1$ (for the MV hedge ratio), E$_3$ (for the Sharpe hedge ratio) and E$_4$ (for the GSV hedge ratio) as the measures of hedging effectiveness
Chen et al. (2001)	Ret$_1$ O$_8$	The paper derives the optimal hedge ratio that maximizes the risk-return function given by $U(R_h) = E[R_h] - V_{\delta,\alpha}(R_h)$. The method can be considered as an extension of the GSV method used by De Jong et al. (1997)
Hung et al. (2006)	Ret$_2$ O$_{10}$	The paper derives the optimal hedge ratio that minimizes the Value-at-Risk for a hedging horizon of length τ given by $Z_\alpha \sigma_h \sqrt{\tau} - E[R_h]\tau$

Notes

A. Return model

(Ret$_1$)

$\Delta V_H = C_s \Delta P_s + C_f \Delta P_f \quad \Rightarrow \quad$ hedge ratio $= H = \frac{C_f}{C_s}$, $C_s =$ units of *spot* commodity and C$_f$ = units of futures contract

(Ret$_2$) $\quad R_h = R_s + hR_f, \quad R_s = \frac{S_t - S_{t-1}}{S_{t-1}}$

(a) $R_f = \frac{F_t - F_{t-1}}{F_{t-1}} \Rightarrow$ hedge ratio: $h = \frac{C_f F_{t-1}}{C_s S_{t-1}}$

(b) $R_f = \frac{F_t - F_{t-1}}{S_{t-1}} \Rightarrow$ hedge ratio: $h = \frac{C_f}{C_s}$.

B. Objective function

(O$_1$) Minimize

$Var(R_h) = C_s^2 \sigma_s^2 + C_f^2 \sigma_f^2 + 2C_s C_f \sigma_{sf}$ or $Var(R_h) = \sigma_s^2 + h^2 \sigma_f^2 + 2h\sigma_{sf}$

(O$_2$) Maximize $\quad E(R_h) - \frac{A}{2} Var(R_h)$

(O$_3$) Maximize $\quad \frac{E(R_h) - R_F}{Var(R_h)}$ (Sharpe ratio), R$_F$ = risk − freeinterestrate

(O$_4$) Maximize $\quad E[U(W)]$, $U(.)$ = utility function, W = terminal wealth

(O$_5$) Minimize $\quad \Gamma_v(R_h), \quad \Gamma_v(R_h) = -vCov\left(R_h, (1 - F(R_h))^{v-1}\right)$

(O$_6$) Maximize $\quad E[R_h] - \Gamma_v(R_h v)$

(O$_7$) Minimize $\quad V_{\delta,\alpha}(R_h) = \int_{-\infty}^{\delta} (\delta - R_h)^\alpha dG(R_h), \quad \alpha > 0$

(O$_8$) Maximize $\quad U(R_h) = E[R_h] - V_{\delta,\alpha}(R_h)$

(O$_9$) Minimize $\quad Var(W_t) = Var\left(\sum_{t=1}^{T} C_{st}\Delta S_t + C_{ft}\Delta F_t\right)$.

(O$_{10}$) Minimize $\quad Z_\alpha \sigma_h \sqrt{\tau} - E[R_h]\tau$

C. Hedging effectiveness

(E$_1$) $\quad e = \left(1 - \frac{Var(R_h)}{Var(R_s)}\right)$

(E$_2$) $\quad e = R_h^{ce} - R_{ss}^{ce}$, R_h^{ce} (R_s^{ce}) = certainty equivalent return of *hedged*(*unhedged*)*portfolio*

(E$_3$) $\quad e = \dfrac{\dfrac{(E[R_h] - R_F)}{Var(R_h)}}{\dfrac{(E[R_s] - R_F)}{Var(R_s)}}$ or $e = \dfrac{(E[R_h] - R_F)}{Var(R_h)} - \dfrac{(E[R_s] - R_F)}{Var(R_s)}$

(E$_4$) $\quad e = 1 - \dfrac{V_{\delta,\alpha}(R_h)}{V_{\delta,\alpha}(R_s)}$.

Appendix B: Empirical Models

References	Commodity	Summary
Ederington (1979)	GNMA futures (1/1976–12/1977), Wheat (1/1976–12/1977), Corn (1/1976–12/1977), T-bill futures (3/1976–12/1977) [weekly data]	The paper uses the Ret_1 definition of return and estimates the minimum- variance hedge ratio (O_1). E_1 is used as a hedging effectiveness measure. The paper uses nearby contracts (3–6 months, 6–9 months and 9–12 months) and a hedging period of 2 weeks and 4 weeks. OLS (M_1) is used to estimate the parameters. Some of the hedge ratios are found not to be different from zero and the hedging effectiveness increases with the length of hedging period. The hedge ratio also increases (closer to unity) with the length of hedging period
Grammatikos and Saunders (1983)	Swiss franc, Canadian dollar, British pound, DM, Yen (1/1974–6/1980) [weekly data]	The paper estimates the hedge ratio for the whole period and moving window (2-year data). It is found that the hedge ratio changes over time. Dummy variables for various sub-periods are used, and shifts are found. The paper uses a random coefficient (M_3) model to estimate the hedge ratio. The hedge ratio for Swiss franc is found to follow a random coefficient model. However, there is no improvement in effectiveness when the hedge ratio is calculated by correcting for the randomness
Junkus and Lee (1985)	Three stock index futures for Kansas City Board of Trade, New York Futures Exchange, and Chicago Mercantile Exchange (5/82–3/83) [daily data]	The paper tests the applicability of four futures hedging models: a variance-minimizing model introduced by Johnson (1960), the traditional one to one hedge, a utility maximization model developed by Rutledge (1972), and a basis arbitrage model suggested by Working (1953). An optimal ratio or decision rule is estimated for each model, and measures for the effectiveness of each hedge are devised. Each hedge strategy performed best according to its own criterion. The Working decision rule appeared to be easy to use and satisfactory in most cases. Although the maturity of the futures contract used affected the size of the optimal hedge ratio, there was no consistent maturity effect on performance. Use of a particular ratio depends on how closely the assumptions underlying the model approach a hedger's real situation

References	Commodity	Summary
Lee et al. (1987)	S&P 500, NYSE, Value Line (1983) [daily data]	The paper tests for the temporal stability of the minimum-variance hedge ratio. It is found that the hedge ratio increases as maturity of the futures contract nears. The paper also performs a functional form test and finds support for the regression of rate of change for discrete as well as continuous rates of change in prices
Cecchetti et al. (1988)	Treasury bond, Treasury bond futures (1/1978–5/1986) [monthly data]	The paper derives the hedge ratio by maximizing the expected utility. A third-order linear bivariate ARCH model is used to get the conditional variance and covariance matrix. A numerical procedure is used to maximize the objective function with respect to the hedge ratio. Due to ARCH, the hedge ratio changes over time. It is found that the hedge ratio changes over time and is significantly less (in absolute value) than the minimum-variance (MV) hedge ratio (which also changes over time). E_2 (certainty equivalent) is used to measure the performance effectiveness. The proposed utility-maximizing hedge ratio performs better than the MV hedge ratio
Cheung et al. (1990)	Swiss franc, Canadian dollar, British pound, German mark, Japanese yen (9/1983–12/1984) [daily data]	The paper uses mean-Gini coefficient ($v = 2$) and mean-variance approaches to analyze the effectiveness of options and futures as hedging instruments. It considers both mean-variance and expected-return mean-Gini coefficient frontiers. It also considers the minimum-variance (MV) and minimum mean-Gini coefficient hedge ratios. The MV and minimum mean-Gini approaches indicate that futures is a better hedging instrument. However, the mean-variance frontier indicates futures to be a better hedging instrument whereas the mean-Gini frontier indicates options to be a better hedging instrument
Baillie and Myers (1991)	Beef, Coffee, Corn, Cotton, Gold, Soybean (contracts maturing in 1982 and 1986) [daily data]	The paper uses a bivariate GARCH model (M_2) in estimating the minimum-variance (MV) hedge ratios. Since the models used are conditional models, the time series of hedge ratios are estimated. The MV hedge ratios are found to follow a unit root process. The hedge ratio for beef is found to be centered around zero. E_1 is used as a hedging effectiveness measure. Both in-sample and out-of-sample effectiveness of the GARCH-based

References	Commodity	Summary
		hedge ratios is compared with a constant hedge ratio. The GARCH-based hedge ratios are found to be significantly better compared to the constant hedge ratio
Malliaris and Urrutia (1991)	British pound, German mark, Japanese yen, Swill franc, Canadian dollar (3/1980–12/1988) [weekly data]	The paper uses regression autocorrelated errors model to estimate the minimum-variance (MV) hedge ratio for the five currencies. Using overlapping moving windows, the time series of the MV hedge ratio and hedging effectiveness are estimated for both ex post (in-sample) and ex ante (out-of-sample) cases. E_1 is used to measure the hedging effectiveness for the ex post case whereas average return is used to measure the hedging effectiveness. Specifically, the average return close to zero is used to indicate a better performing hedging strategy. In the ex post case, the 4-week hedging horizon is more effective compared to the 1-week hedging horizon. However, for the ex ante case the opposite is found to be true
Benet (1992)	Australian dollar, Brazilian cruzeiro, Mexican peso, South African rand, Chinese yuan, Finish markka, Irish pound, Japanese yen (8/1973–12/1985) [weekly data]	This paper considers direct and cross hedging, using multiple futures contracts. For minor currencies, the cross hedging exhibits a significant decrease in performance from ex post to ex ante. The minimum-variance hedge ratios are found to change from one period to the other except for the direct hedging of Japanese yen. On the ex ante case, the hedging effectiveness does not appear to be related to the estimation period length. However, the effectiveness decreases as the hedging period length increases
Kolb and Okunev (1992)	Corn, Copper, Gold, German mark, S&P 500 (1989) [daily data]	The paper estimates the mean extended-Gini (MEG) hedge ratio (M_9) with v ranging from 2 to 200. The MEG hedge ratios are found to be close to the minimum-variance hedge ratios for a lower level of risk parameter v (for v from 2 to 5). For higher values of v, the two hedge ratios are found to be quite different. The hedge ratios are found to increase with the risk aversion parameter for S&P 500, Corn, and Gold. However, for Copper and German mark, the hedge ratios are found to decrease with the risk aversion parameter. The hedge ratio tends to be more stable for higher levels of risk

(continued)

References	Commodity	Summary
Kolb and Okunev (1993)	Cocoa (3/1952–1976) for four cocoa-producing countries (Ghana, Nigeria, Ivory Coast, and Brazil) [March and September data]	The paper estimates the Mean-MEG (M-MEG) hedge ratio (M_{12}). The paper compares the M-MEG hedge ratio, minimum-variance hedge ratio, and optimum mean-variance hedge ratio for various values of risk aversion parameters. The paper finds that the M-MEG hedge ratio leads to reverse hedging (buy futures instead of selling) for v less than 1.24 (Ghana case). For high-risk aversion parameter values (high v) all hedge ratios are found to converge to the same value
Lien and Luo (1993a)	S&P 500 (1/1984–12/1988) [weekly data]	The paper points out that the mean extended-Gini (MEG) hedge ratio can be calculated either by numerically optimizing the MEG coefficient or by numerically solving the first-order condition. For $v = 9$ the hedge ratio of -0.8182 is close to the minimum-variance (MV) hedge ratio of -0.8171. Using the first-order condition, the paper shows that for a large v the MEG hedge ratio converges to a constant. The empirical result shows that the hedge ratio decreases with the risk aversion parameter v. The paper finds that the MV and MEG hedge ratio (for low v) series (obtained by using a moving window) are more stable compared to the MEG hedge ratio for a large v. The paper also uses a non-parametric Kernel estimator to estimate the cumulative density function. However, the kernel estimator does not change the result significantly
Lien and Luo (1993b)	British pound, Canadian dollar, German mark, Japanese yen, Swiss franc (3/1980–12/1988), MMI, NYSE, S&P (1/1984–12/1988) [weekly data]	This paper proposes a multi-period model to estimate the optimal hedge ratio. The hedge ratios are estimated using an error-correction model. The spot and futures prices are found to be cointegrated. The optimal multi-period hedge ratios are found to exhibit a cyclical pattern with a tendency for the amplitude of the cycles to decrease. Finally, the possibility of spreading among different market contracts is analyzed. It is shown that hedging in a single market may be much less effective than the optimal spreading strategy
Ghosh (1993)	S&P futures, S&P index, Dow Jones Industrial average, NYSE composite index	All the variables are found to have a unit root. For all three indices the same S&P 500 futures contracts are used (cross hedging). Using the Engle-Granger two-step test, the S&P 500 futures price is found to

(continued)

References	Commodity	Summary
	(1/1990–12/1991) [daily data]	be cointegrated with each of the three spot prices: S&P 500, DJIA, and NYSE. The hedge ratio is estimated using the error-correction model (ECM) (M_4). Out-of-sample performance is better for the hedge ratio from the ECM compared to the Ederington model
Sephton (1993a)	Feed wheat, Canola futures (1981–82 crop year) [daily data]	The paper finds unit roots on each of the cash and futures (log) prices, but no cointegration between futures and spot (log) prices. The hedge ratios are computed using a four-variable GARCH(1,1) model. The time series of hedge ratios are found to be stationary. Reduction in portfolio variance is used as a measure of hedging effectiveness. It is found that the GARCH-based hedge ratio performs better compared to the conventional minimum-variance hedge ratio
Sephton (1993b)	Feed wheat, Feed barley, Canola futures (1988/89) [daily data]	The paper finds unit roots on each of the cash and futures (log) prices, but no cointegration between futures and spot (log) prices. A univariate GARCH model shows that the mean returns on the futures are not significantly different from zero. However, from the bivariate GARCH canola is found to have a significant mean return. For canola the mean variance utility function is used to find the optimal hedge ratio for various values of the risk aversion parameter. The time series of the hedge ratio (based on bivariate GARCH model) is found to be stationary. The benefit in terms of utility gained from using a multivariate GARCH decreases as the degree of risk aversion increases
Kroner and Sultan (1993)	British pound, Canadian dollar, German mark, Japanese yen, Swiss franc (2/1985–2/1990) [weekly data]	The paper uses the error-correction model with a GARCH error (M_5) to estimate the minimum-variance (MV) hedge ratio for the five currencies. Due to the use of conditional models, the time series of the MV hedge ratios are estimated. Both within-sample and out-of-sample evidence shows that the hedging strategy proposed in the paper is potentially superior to the conventional strategies
Hsin et al. (1994)	British pound, German mark, Yen, Swiss franc (1/1986–12/1989) [daily data]	The paper derives the optimum mean-variance hedge ratio by maximizing the objective function O_2. The hedging horizons of 14, 30, 60, 90, and 120 calendar days are considered to compare the

References	Commodity	Summary
		hedging effectiveness of options and futures contracts. It is found that the futures contracts perform better than the options contracts
Shalit (1995)	Gold, silver, copper, aluminum (1/1977–12/1990) [daily data]	The paper shows that if the prices are jointly normally distributed, the mean extended-Gini (MEG) hedge ratio will be same as the minimum-variance (MV) hedge ratio. The MEG hedge ratio is estimated using the instrumental variable method. The paper performs normality tests as well as the tests to see if the MEG hedge ratios are different from the MV hedge ratios. The paper finds that for a significant number of futures contracts the normality does not hold and the MEG hedge ratios are different from the MV hedge ratios
Geppert (1995)	German mark, Swiss franc, Japanese yen, S&P 500, Municipal Bond Index (1/1990–1/1993) [weekly data]	The paper estimates the minimum-variance hedge ratio using the OLS as well as the cointegration methods for various lengths of hedging horizon. The in-sample results indicate that for both methods the hedging effectiveness increases with the length of the hedging horizon. The out-of-sample results indicate that in general the effectiveness (based on the method suggested by Malliaris and Urrutia (1991)) decreases as the length of the hedging horizon decreases. This is true for both the regression method and the decomposition method proposed in the paper. However, the decomposition method seems to perform better than the regression method in terms of both mean and variance
De Jong et al. (1997)	British pound (12/1976–10/1993), German mark (12/1976–10/1993), Japanese yen (4/1977–10/1993) [daily data]	The paper compares the minimum-variance, generalized semivariance and Sharpe hedge ratios for the three currencies. The paper computes the out-of-sample hedging effectiveness using non-overlapping 90-day periods where the first 60 days are used to estimate the hedge ratio and the remaining 30 days are used to compute the out-of-sample hedging effectiveness. The paper finds that the naïve hedge ratio performs better than the model based hedge ratios
Lien and Tse (1998)	Nikkei stock average (1/1989–8/1996) [daily data]	The paper shows that if the rates of change in spot and futures prices are bivariate normal and if the futures price follows a martingale process, then the generalized

References	Commodity	Summary	References	Commodity	Summary
		semivariance (GSV) (referred to as lower partial moment) hedge ratio will be same as the minimum-variance (MV) hedge ratio. A version of the bivariate asymmetric power ARCH model is used to estimate the conditional joint distribution, which is then used to estimate the time varying GSV hedge ratios. The paper finds that the GSV hedge ratio significantly varies over time and is different from the MV hedge ratio			Furthermore, the expected value of the futures price change is found to be significantly different from zero. It is also found that for a high level of risk aversion, the M-MEG hedge ratio converges to the MV hedge ratio whereas the M-GSV hedge ratio converges to a lower value
Lien and Shaffer (1999)	Nikkei (9/86–9/89), S&P (4/82–4/85), TOPIX (4/90–12/93), KOSPI (5/96–12/96), Hang Seng (1/87–12189), IBEX (4/93–3/95) [daily data]	This paper empirically tests the ranking assumption used by Shalit (1995). The ranking assumption assumes that the ranking of futures prices is the same as the ranking of the wealth. The paper estimates the mean extended-Gini (MEG) hedge ratio based on the instrumental variable (IV) method used by Shalit (1995) and the true MEG hedge ratio. The true MEG hedge ratio is computed using the cumulative probability distribution estimated employing the kernel method instead of the rank method. The paper finds that the MEG hedge ratio obtained from the IV method to be different from the true MEG hedge ratio. Furthermore, the true MEG hedge ratio leads to a significantly smaller MEG coefficient compared to the IV-based MEG hedge ratio	Hung et al. (2006)	S&P 500 (01/1997–12/1999) [daily data]	The paper proposes minimization of Value-at-Risk in deriving the optimum hedge ratio. The paper finds cointegrating relationship between the spot and futures returns and uses bivariate constant correlation GARCH(1,1) model with error correction term. The paper compares the proposed hedge ratio with MV hedge ratio and hedge ratio (HKL hedge ratio) proposed by Hsin et al. (1994). The paper finds the performance of the proposed hedge ratio to be similar to the HKL hedge ratio. Finally, the proposed hedge ratio converges to the MV hedge ratio for high risk-averse levels
			Lee and Yoder (2007)	Nikkei 225 and Hang Send index futures (01/1989–12/2003) [weekly data]	The paper proposes regime-switching time varying correlation GARCH model and compares the resulting hedge ratio with constant correlation GARCH and time-varying correlation GARCH. The proposed model is found to outperforms the other two hedge ratio in both in-sample and out-of-sample for both contracts
Lien and Tse (2000)	Nikkei stock average (1/1988–8/996) [daily data]	The paper estimates the generalized semivariance (GSV) hedge ratios for different values of parameters using a non-parametric kernel estimation method. The kernel method is compared with the empirical distribution method. It is found that the hedge ratio from one method is not different from the hedge ratio from another. The Jarque-Bera (1987) test indicates that the changes in spot and futures prices do not follow normal distribution	Lien and Shrestha (2007)	23 different futures contracts (sample period depends on contracts) [daily data]	This paper proposes wavelet base hedge ratio to compute the hedge ratios for different hedging horizons (1-day, 2-day, 4-day, 8-day, 16 day, 32-day, 64-day, 128-day; and 256-day and longer). It is found that the wavelet based hedge ratio and the error-correction based hedge ratio are larger than MV hedge ratio. The performance of wavelet based hedge ratio improves with the length of hedging horizon
Chen et al. (2001)	S&P 500 (4/1982–12/1991) [weekly data]	The paper proposes the use of the M-GSV hedge ratio. The paper estimates the minimum-variance (MV), optimum mean-variance, Sharpe, mean extended-Gini (MEG), generalized semivariance (GSV), mean-MEG (M-MEG), and mean-GSV (M-GSV) hedge ratios. The Jarque-Bera (1987) Test and D'Agostino (1971) D statistic indicate that the price changes are not normally distributed.	Lien and Shrestha (2010)	22 different futures contracts (sample period depends on contracts) [daily data]	The paper proposes the hedge ratio based on skew-normal distribution (SKN hedge ratio). The paper also estimates the semi-variance (lower partial moment (LPM)) hedge ratio and MV hedge ratio among other hedge ratios. SKN hedge ratios are found to be different from the MV hedge ratio based on normal distribution. SKN hedge ratio performs better than LPM hedge

		ratio for long hedger especially for the out-of-sample cases

Notes

A. Minimum-variance hedge ratio

A.1. OLS

(M$_1$): $\Delta S_t = a_0 + a_1 \Delta F_t + e_t$:   *Hedge ratio* $= a_1$

$\qquad\quad R_s = a_0 + a_1 R_f + e_t$:   *Hedge ratio* $= a_1$

A.2. Multivariate skew-normal

(M$_2$):   The return vector $Y = \begin{bmatrix} R_s \\ R_f \end{bmatrix}$ is assumed to have skew-normal

distribution with covariance matrix V:

$\qquad\qquad$ *Hedge ration* $= H_{skn} = \dfrac{V(1,2)}{V(2,2)}$

A.3. ARCH/GARCH

(M$_3$): $\begin{bmatrix} \Delta S_t \\ \Delta F_t \end{bmatrix} = \begin{bmatrix} \mu_1 \\ \mu_2 \end{bmatrix} + \begin{bmatrix} e_{1t} \\ e_{2t} \end{bmatrix}$,$\qquad\qquad e_t | \Omega_{t-1} \sim N(0, H_t)$,

$H_t = \begin{bmatrix} H_{11,t} & H_{12,t} \\ H_{12,t} & H_{22,t} \end{bmatrix}$, *Hedge ratio* $= H_{12,t}/H_{22,t}$

A.4. Regime-switching GARCH

(M$_4$):   The transition probabilities are given by

$\qquad\quad \Pr(s_t = 1 | s_{t-1} = 1) = \dfrac{e^{p_0}}{1 + e^{p_0}}$ & $\Pr(s_t = 2 | s_{t-1} = 2) = \dfrac{e^{q_0}}{1 + e^{q_0}}$

$\qquad$ The GARCH model: Two-series GARCH model with first series as return on futures.

$H_{t,s_t} = \begin{bmatrix} h_{1,t,s_t} & 0 \\ 0 & h_{2,t,s_t} \end{bmatrix} \begin{bmatrix} 1 & \rho_{t,s_t} \\ \rho_{t,s_t} & 1 \end{bmatrix} \begin{bmatrix} h_{1,t,s_t} & 0 \\ 0 & h_{2,t,s_t} \end{bmatrix}$

$h_{1,t,s_t}^2 = \gamma_{1,s_t} + \alpha_{1,s_t} e_{1,t-1}^2 + \beta_{1,s_t} h_{1,t-1}^2$,

$h_{2,t,s_t}^2 = \gamma_{2,s_t} + \alpha_{2,s_t} e_{2,t-1}^2 + \beta_{2,s_t} h_{2,t-1}^2$

$\rho_{t,s_t} = (1 - \theta_{1,s_t} - \theta_{2,s_t})\rho + \theta_{1,s_t}\rho_{t-1} + \theta_{2,s_t}\varphi_{t-1}$

$\phi_{t-1} = \dfrac{\sum_{j=1}^{2} \varepsilon_{1,t-j}\varepsilon_{2,t-j}}{\sqrt{\left(\sum_{j=1}^{2}\varepsilon_{1,t-j}^2\right)\left(\sum_{j=1}^{2}\varepsilon_{2,t-j}^2\right)}}$, $\varepsilon_{i,t} = \dfrac{e_{i,t}}{h_{it}}$, $\theta_1, \theta_2 \geq 0$

& $\theta_1 + \theta_2 \leq 1$,   *Hedge ratio* $= \dfrac{H_{t,s_t}(1,2)}{H_{t,s_t}(2,2)}$

A.5. Random coefficient

(M$_5$): $\Delta S_t = \beta_0 + \beta_t \Delta F_t + e_t$

$\qquad\quad \beta_t = \bar{\beta} + v_t$,   *Hedge ratio* $= \bar{\beta}$

A.6. Cointegration and error-correction

(M$_6$): $S_t = a + bF_t + u_t$

$\qquad\quad \Delta S_t = \rho u_{t-1} + \beta \Delta F_t + \sum_{i=1}^{m} \delta_i \Delta F_{t-i} + \sum_{j=1}^{n} \theta_i \Delta S_{t-j} + e_j$,

EC Hedge ratio $= \beta$

A.7. Error-correction with GARCH

(M$_7$):

$\begin{bmatrix} \Delta \log_e(S_t) \\ \Delta \log_e(F_t) \end{bmatrix} = \begin{bmatrix} \mu_1 \\ \mu_2 \end{bmatrix} + \begin{bmatrix} \alpha_s(\log_e(S_{t-1}) - \log_e(F_{t-1})) \\ \alpha_f(\log_e(S_{t-1}) - \log_e(F_{t-1})) \end{bmatrix} + \begin{bmatrix} e_{1t} \\ e_{2t} \end{bmatrix}$,

$e_t | \Omega_{t-1} \sim N(0, H_t)$, $H_t = \begin{bmatrix} H_{11,t} & H_{12,t} \\ H_{12,t} & H_{22,t} \end{bmatrix}$

$\qquad\qquad$ *Hedge ratio* $= h_{t-1} = H_{12,t}/H_{22,t}$

A.8. Common stochastic trend

(M$_8$): $S_t = A_1 P_t + A_2 \tau_t$, $F_t = B_1 P_t + B_2 \tau_t$, $P_t = P_{t-1} + w_t$,

$\tau_t = \alpha_1 \tau_{t-1} + v_t$, $0 \leq |\alpha_1| < 1$,

$\qquad$ *Hedge ratio for k-period investment horizon* $=$

$H_J^* = \dfrac{A_1 B_1 k \sigma_w^2 + 2A_2 B_2 \left(\frac{(1-\alpha^k)}{1-\alpha^2}\right)\sigma_v^2}{B_1^2 k \sigma_w^2 + 2B_2^2 \left(\frac{(1-\alpha^k)}{1-\alpha^2}\right)\sigma_v^2}$.

B. Optimum mean-variance hedge ratio

(M$_9$):   *Hedge ratio* $= h_2 = -\dfrac{C_f^* F}{C_s S} = -\left[\dfrac{E(R_f)}{A\sigma_f^2} - \rho \dfrac{\sigma_s}{\sigma_f}\right]$, where the

moments $E[R_f]$, σ_s and σ_f are estimated by sample moments

C. Sharpe hedge ratio

(M$_{10}$):   *Hedge ratio* $= h_3 = -\dfrac{\left(\frac{\sigma_x}{\sigma_f}\right)\left[\frac{\sigma_s}{\sigma_f}\left(\frac{E(R_f)}{E(R_s)-i}\right) - \rho\right]}{\left[1 - \frac{\sigma_x}{\sigma_f}\left(\frac{E(R_f)\rho}{E(R_s)-i}\right)\right]}$, where the moments

and correlation are estimated by their sample counterparts

D. Mean-Gini coefficient based hedge ratios

(M$_{11}$):   The hedge ratio is estimated by numerically minimizing the following mean extended-Gini coefficient, where the cumulative probability distribution function is estimated using the rank function

$\Delta S_t = \rho u_{t-1} + \beta \Delta F_t + \sum_{i=1}^{m} i \Delta F_{t-1} + \sum_{j=1}^{n} \phi_i \Delta S_{t-j} + e_j$, EC   *Hedge ratio* $= \beta$

(M$_{12}$):   The hedge ratio is estimated by numerically solving the first-order condition, where the cumulative probability distribution function is estimated using the rank function

(M$_{13}$):   The hedge ratio is estimated by numerically solving the first-order condition, where the cumulative probability distribution function is estimated using the kernel-based estimates

(M$_{14}$):   The hedge ratio is estimated by numerically maximizing the following function

$\qquad U(R_h) = E(R_h) - \Gamma_v(R_h)$,

$\qquad$ where the expected values and the mean extended-Gini coefficient are replaced by their sample counterparts and the cumulative probability distribution function is estimated using the rank function

E. Generalized semivariance based hedge ratios

(M$_{15}$):   The hedge ratio is estimated by numerically minimizing the following sample generalized hedge ratio

$\qquad V_{\delta,\alpha}^{sample}(R_h) = \dfrac{1}{N}\sum_{i=1}^{N}(\delta - R_{h,i})^{\alpha} U(\delta - R_{h,i})$,$\qquad$ where

$U(\delta - R_{h,i}) = \begin{cases} 1 \text{ for } \delta \geq R_{h,i} \\ 0 \text{ for } \delta < R_{h,i} \end{cases}$

(M$_{16}$):   The hedge ratio is estimated by numerically maximizing the following function

$U(R_h) = R_h - V_{\delta,\alpha}^{sample}(R_h)$.

E. Minimum Value-at-Risk hedge ratio

(M$_{17}$):   The hedge ratio is estimated by minimizing the following Value-at-Risk

$\qquad VaR(R_h) = Z_\alpha \sigma_h \sqrt{\tau} - E[R_h]\tau$

$\qquad$ The resulting hedge ratio is given by

$\qquad h^{VaR} = \rho \dfrac{\sigma_s}{\sigma_f} - E[R_f]\dfrac{\sigma_s}{\sigma_f}\sqrt{\dfrac{1 - \rho^2}{Z_\alpha^2 \sigma_f^2 - E[R_f]^2}}$

Abstract

The two well-known approaches for credit risk modeling, structural and reduced form approaches, have their advantages and disadvantages. Due to the fundamentally different assumptions of the two approaches, the structural models are used for default prediction that focuses on equity prices and reduced form models are used for credit derivatives pricing that focuses on debt values. In this paper, via a simple discrete binomial structure, we provide a unified view of the two approaches. In particular, in our formulation, the pricing formulas for risky debts are identical under the two approaches. The two approaches differ in only the recovery assumption. This result makes comparison of various models empirically possible. We demonstrate, in a credit derivative example that is sensitive to the recovery assumption, how different recovery assumptions impact its prices.

75.1 Introduction

There have been two well-known approaches, structural and reduced form, for credit risk modeling. Reduced form models, represented by Jarrow and Turnbull (1995) and Duffie and Singleton (1997, 1999) assume defaults (or credit events) occur exogenously (usually by a Poisson process) and a separately specified recovery is paid upon default.[1] Structural models, on the other hand, assume defaults occur when the value of the firm falls below a certain default point and a certain recovery is paid. The "true structural" model of Geske (1977) and Geske and Johnson (1984) assumes the default point to be the market value of debt that is endogenously

computed and the firm value is the recovery. This formulation leads to multi-variate probability functions. The "barrier structural" models, pioneered by Black and Cox (1976), obtain uni-variate valuation formulas by assuming an exogenous default point and an exogenous recovery amount.[2]

Structural models for credit risk modeling have been mainly used for default prediction[3] or capital structure analysis while reduced form models are mainly used by investment banks to price credit derivatives.[4] This is because structural models rely on the information from equity prices while reduced form models from debt prices. Furthermore, reduced form models are more computationally efficient due to their exogenous default and recovery assumptions, which

---

[1] Other reduced form models include, among others, Duffie and Lando (1997), Jarrow et al. (1997), Jarrow and Yu (2001), Lando (1998), Madan and Unal (2000), and Schönbucher (1998).

*I would like to thank Jay Huang and Sanlin Chung for their helpful comments.

[2] Other structural models include, for example, Anderson and Sundaresan (1996), Leland and Toft (1996), Longstaff and Schwartz (1995), Zhou (2001), and Bélanger et al. (2002). Readers can also find a more thorough survey by Uhrig-Homburg (2002).

[3] For example, see KMV's EDF and Moody's RiskCalc.

[4] It should be noted that structural models are also proposed for pricing risky bonds. However, they have never gained support from the industry due to the difficulty in calibration.

are important for pricing credit derivatives. Another reason for the reduced form models to be chosen by investment banks is its relative ease to incorporate the term structure of the default free interest rates.[5]

In this paper, we clarify the difference between the "true structural" model of Geske (1977) and Gseke and Johnson (1984) in which defaults occur when the (market) value of the firm falls below the (market) value of debt and the "barrier structural model" in which defaults occur when the value of the firm crosses an exogenously pre-defined barrier. The former valuation leads to multi-variate distributions while the latter is a univariate valuation.[6] We then show that reduced-form and structural models can be made consistent under a simple discrete binomial formulation. Under this binomial formulation, the two sets of models have identical pricing formulas for risky debts. The only difference is different recovery assumptions. This result makes it possible to compare various models. In an application, we use credit default swaps to examine the impact of different recovery assumptions.

It is generally understood that structural models are difficult to calibrate. For example, for an n-period bond, we need n-dimensional probability functions, which are computationally expensive. However, in this paper, we employ the standard one-dimensional equity binomial model, which can be accurate to the second decimal place in 50 steps.

The remaining of the paper is organized as follows. Section 75.2 lays out the basic valuation equations. In particular, we specify the forward measure technique to incorporate stochastic interest rates. Section 75.3 presents the binomial framework under which all models share the same valuation formula. In Section 75.4, we discuss calibration issues of various models and perform model comparison. Section 75.5 concludes

75.2 Basic Setup

Define a T-maturity default-free pure discount bond price at current time t, denoted $P(t,T)$ with $P(T,T)=1$ for all T. Also define a set of dates: $0 = T_0 < T_1 < \cdots < T_{N-1} < T_N$. For simplicity and without loss of generality, we also assume $h = T_i - T_{i-1}$ for all $i = 1, \cdots, N$. Let $\ell(T_i, T_j)$, $0 \le i < j \le N$, represent the default free "term" interest rate (annualized) over $[T_i, T_j]$. Hence, by definition:

$$\ell(T_i, T_j) = \frac{1}{T_j - T_i}\left(\frac{1}{P(T_i, T_j)} - 1\right) \quad (75.1)$$

Denote by Q the risk neutral measure under which defined the instantaneous short rate r. Then we have:

$$P(t,T) = E_t^Q[\Lambda(t,T)] \quad (75.2)$$

where

$$\Lambda(t,s) = \exp\left(-\int_t^s r(u)du\right), 0 \le t < s \le T \text{ and}$$

$E_t^Q[\cdot]$ represents the expectation conditional on the information set at time t under the risk neutral measure Q.

For the sake of convenience, we further define T_n-forward measure, denoted by F_n, to be equivalent to the measure Q and the corresponding Radon-Nikodym derivative is given by[7]:

$$\frac{dF_n}{dQ} = \frac{\Lambda(t,T_n)}{P(t,T_n)} \quad (75.3)$$

Under (75.3) the forward price is merely the forward expectation of the bond price:

$$F(0,t,s) = E_0^{F_t}[P(t,s)] = \frac{P(0,s)}{P(0,t)} \quad (75.4)$$

and so is the discrete forward rate:

$$E_0^{F_t}[l(u,t)h] = \frac{1}{F(0,u,t)} - 1 \quad (75.5)$$

Finally, we reiterate the separation of expectation using the forward measure:

$$\begin{aligned} E_0^Q[\Lambda(0,t)I_{\{t<\tau\}}] &= E_0^Q[\Lambda(0,t)]E_0^{F_t}[I_{\{t<\tau\}}] \\ &= P(0,t)Q(0,t) \end{aligned} \quad (75.6)$$

where τ is the default time and:

$$Q(0,t) = E_0^{F_t}[I_{\{t<\tau\}}] \quad (75.7)$$

as the survival probability under the forward measure where $I_{\{\cdot\}}$ is an indicator function and τ is the default time. Equation 75.6 represents the present of \$1 paid if there is no default and 0 otherwise. Hence, it is also known as the risky discount factor.

---

[5] The two most known reduced form models by Jarrow and Turnbull (1995) and Duffie and Singleton (1999) can both be easily incorporated into existing term structure models.

[6] Bélanger et al. (2002) provide a unified model that nests all barrier structural models. This paper can be viewed as an extension of their work.

[7] For the forward measure, see, for example, Jamshidian (1987) and Hull (2000).

75.3 The Unified Model

The unified model is a simple binomial model that defines default and no default states at every period. This model is general to accommodate any form of recovery upon default and any form of cash flows under no default.
Hence, their solution to the risky fixed rate coupon bond can be written as:

$$
\begin{aligned}
V(0,T_n) &= E_0^Q\Big[\sum\nolimits_{i=1}^{n}\Lambda(0,T_i)c_nhI_{\{\tau>T_i\}} + \Lambda(0,T_n)I_{\{\tau>T_n\}} \\
&\quad + \Lambda(0,\tau)w_n(A(\tau),r(\tau))I_{\{\tau<T_n\}}\Big] \\
&= \sum\nolimits_{i=1}^{n}P(0,T_i)Q(0,T_i)c_nh + P(0,T_n)Q(0,T_n) + R_n(0)
\end{aligned}
$$

(75.8)

where c_n is the fixed coupon, $w_n(\cdot,\cdot)$, which is a function of some state variable A and interest rate r, represents the recovery amount upon default, and $R_n(0)$ is the current value of expected recovery. Note that the first two terms of the second line follows directly form (75.6) and (75.7). They represent the value of coupons and face value. The last term represents the current recover value, which is an expected present value of the recovery amount upon default, a function of some state variable(s), A and the risk free interest rate, r.

The solution to the risky floating rate bond is:

$$
\begin{aligned}
V^*(0,T_n) &= E_0^Q\Big[\sum\nolimits_{i=1}^{n}\Lambda(0,T_i)\ell(T_{i-1},T_i)hI_{\{\tau>T_i\}} \\
&\quad + \Lambda(0,T_n)I_{\{\tau>T_n\}} + \Lambda(0,\tau)w_n(A(\tau),r(\tau))I_{\{\tau<T_n\}}\Big] \\
&= \sum\nolimits_{i=1}^{n}P(0,T_i)Q(0,T_i)[F(0,T_{i-1},T_i)^{-1}-1] \\
&\quad + h\gamma_{i-1,i} + P(0,T_n)Q(0,T_n) + R_n(0)
\end{aligned}
$$

(75.9)

where

$$
\gamma_{i-1,i} = \mathrm{cov}[\ell(T_{i-1},T_i),I_{\{\tau>T_i\}}]
$$

is the covariance under the forward measure between the random interest rate and the default event, which is usually assumed 0. It is generally accepted that default probability is positively correlated with interest rates; but default events

(or equivalently, default time) are independent of interest rates. The second line of (75.9) comes directly from (75.5). As we can see, the difference between a floater and a fixed rate bond is the coupon payment series, where the former is taken from the forward curve and the latter is a fixed constant. Hence, for the rest of the paper, we simply concentrate on fixed rate bond.

It is not unreasonable to assume that defaults can occur only at discrete points (i.e. coupon payment times). Usually the company does not have to declare default if there is no cash pressure. This assumption validates the use of the Geske-Johnson structural model. So far, we have not used any model specification. The remainder of this section, presents $V(0,T_n)$ in various model specifications.

75.3.1 The Jarrow-Turnbull Model

The Jarrow-Turnbull model assumes that a fixed recovery is paid at maturity regardless of the time of default. Hence, the closed form solution exists for the coupon bond as follows:

$$
\begin{aligned}
V_{\mathrm{JT}}(0,T_n) &= \sum\nolimits_{i=1}^{n}P(0,T_i)Q(0,T_i)c_nh + P(0,T_n)Q(0,T_n) \\
&\quad + w_nP(0,T_n)[1-Q(0,T_n)]
\end{aligned}
$$

(75.10)

In such a case, $R_n(0) = w_nP(0,T_n)[1-Q(0,T_n)]$. This model is also recognized as "recovery of proportional to par". An extended Jarrow-Turnbull model of the following is usually used in the industry in which defaults are allowed only at coupon times and a fixed recovery is paid upon default.

$$
\begin{aligned}
\Phi_{\mathrm{JT}}(0,T_n) &= \sum\nolimits_{i=1}^{n}P(0,T_i)Q(0,T_i)c_nh + P(0,T_n)Q(0,T_n) \\
&\quad + w_n(T_i)P(0,T_i)[Q(0,T_{i-1})-Q(0,T_i)]
\end{aligned}
$$

(75.11)

In such a case, $R_n(0) = \Sigma_{i=1}^{n}w_n(T_i)P(0,T_i)[Q(0,T_{i-1}) -Q(0,T_i)]$. In many cases, continuous default is necessary, hence a continuous version of recovery is also commonly used: $R_n(0) = \int_0^{T_n}w_n(t)P(0,t)[-dQ(0,t)]$.

75.3.2 The Duffie-Singleton Model

The Duffie-Singleton model assumes recovery is paid immediately upon default and equals a fraction of what the bond is worth immediately prior to default. In our formulation, it means:

$$
w_n(t) = \delta V(t,T_n)
$$

(75.12)

where δ is the constant recovery ratio on the value of the bond prior to default. Substituting this result back to (75.8), we get:

$$V_{\mathrm{DS}}(0, T_n) = \sum_{i=1}^{n} P(0, T_i) Q^*(0, T_i) c_n h + P(0, T_n) Q^*(0, T_n)$$

(75.13)

where c_n is the fixed coupon and

$$Q^*(0, T_i) = E_0^{F_i} \left[e^{-(1-\delta) \int_0^{T_i} \lambda(t) dt} \right] = \begin{cases} Q(0, T_i) e^{\delta \int_0^{T_i} \lambda(t) dt} \\ Q(0, T_i)^{1-\delta} \end{cases}$$

(75.14)

where $\lambda(t)$ is the Poisson intensity parameter.[8] Default occurs when there is a jump with a probability $\lambda(t) dt$ over the period dt. It can be seen that the Duffie-Singleton model cannot differentiate the survival probability from the recovery, a drawback of the model. However, the solution represented by (75.13) and (75.14) is a closed form solution of the affine style, more easily to derive closed form solutions when the recovery ratio and the intensity parameter are random.

It is clear that in the Duffie-Singleton model, recovery is blended into survival probabilities. In other words, recovery in the Duffie-Singleton model contains survival probabilities. Formally, we can write recovery as:

$$R_n(0) = \sum_{i=1}^{n} P(0, T_i) Q(0, T_i) [M(0, T_i) - 1] c_n h + P(0, T_n) Q^*(0, T_n)$$

(75.15)

where[9]

---

[8] If the intensity parameter and/or the recovery rate are random, then (75.14) becomes:

$$Q^*(0, T_i) = E_0^{F_i} \left[e^{-(1-\delta) \int_0^{T_i} \lambda(t) dt} \right]$$

(75.14a)

[9] If the intensity parameter and/or the recovery rate are random, then we have:

$$M(0, t) = \tilde{E}_0^{F_t} \left[e^{\delta \int_0^{t} \lambda(u) du} \right]$$

where

$$\frac{dF_i}{d\tilde{F}_i} = \frac{e^{-\int_0^{T_i} \lambda(t) dt}}{Q(0, T_i)}$$

$$M(0, t) = e^{\delta \int_0^{t} \lambda(u) du}$$

75.3.3 The Extended Merton Model

The structural models can be traced back to Black and Scholes (1973) and Merton (1974) who observe that the company's equity is a European call option and hence the single-maturity-date debt contains default risk identical to a covered call. The recovery in the Black-Scholes-Merton model is therefore the firm value if default occurs at maturity. To extend the single period model of Black-Scholes and Merton, as mentioned earlier, there are two approaches. The "barrier structural" models assume an exogenous default barrier. Default is defined as the asset value crossing such a barrier.[10] The extension along this is pioneered by Black and Cox (1976), followed by Leland and Toft (1996) and Longstaff and Schwartz (1995), and recently extended by Bélanger et al. (2002). Another is a "pure structural" model by Geske (1977) and Geske and Johnson (1984) who adopt the compound option approach and treat default as the inability of the company to fulfill its debt obligations (i.e. negative equity value).

In this sub-section, we include multi-period debt structure in the Merton model. We assume defaults occur if the firm fails to meet its coupon obligations at any give time. Since the coupon obligations are exogenously given, the "barrier structural" models can be viewed as the continuous time limit of what is described here.

Consistent with our discrete setup, let $X_1, \cdots, X_n$ be the series of external barriers, crossing which by the firm value represents default. These discrete time barriers can be interpreted as cash obligations at each time and failure to make the obligation results in default of the firm. These cash obligations can be regarded as a series of zero coupon bonds issued by the firm. The values of assets and debts (zero coupon) are labeled as $A(t)$, and $D(t, T_n)$ respectively for an arbitrary t. Default is defined as $A \times (T_i) < X_i$ at time T_i. To obtain closed form solutions, we assume the continuity of $A(t)$, as by Geske (1977) and Geske and Johnson (1984). To arrive at closed form results, we need to assume a log normal process for the firm's asset value and a normal process for the instantaneous short rate:

---

[10] The barrier-based structural models are particularly popular in industry. See, for example, KMV (recently acquired by Moody's) and CreditGrades.

$$\begin{bmatrix} \dfrac{dA(t)}{A(t)} \\ dr(t) \end{bmatrix} = \begin{bmatrix} r(t) \\ \mu(r,t) \end{bmatrix} dt + \begin{bmatrix} \sigma_A & 0 \\ 0 & \sigma_r \end{bmatrix}$$
$$\times \begin{bmatrix} \sqrt{1-\rho_{Ar}^2} & \rho_{Ar} \\ 0 & 1 \end{bmatrix} \times \begin{bmatrix} dW_A^Q(t) \\ dW_r^Q(t) \end{bmatrix} \quad (75.16)$$

where σ_A, σ_r, and ρ_{Ar} are constants, and $dW_A^Q dW_r^Q = 0$. From (75.16), we know that the correlation between the (log) asset value and the interest rate is ρ_{Ar}. Also note that both $W_A^Q(t)$ and $W_r^Q(t)$ are Wiener processes under the Q measure. Applying Ito's lemma to (75.2) in Section 75.2, we obtain that:

$$\begin{aligned} \dfrac{dP(t,T)}{P(t,T)} &= \dfrac{1}{P(t,T)}\left[\dfrac{\partial P(t,T)}{\partial r}\mu(r,t) + \dfrac{1}{2}\dfrac{\partial^2 P(t,T)}{\partial r^2}\sigma_r^2 + \dfrac{\partial P(t,T)}{\partial t}\right]dt \\ &\quad + \dfrac{1}{P(t,T)}\dfrac{\partial P(t,T)}{\partial r}\sigma_r dW_r^Q(t) \\ &\equiv r(t)dt + \sigma_P(r,t,T)dW_r^Q(t) \end{aligned}$$
$$(75.17)$$

The Gaussian models that satisfy (75.17) are Vasicek (1977), Ho and Lee (1986), and Hull and White (1990), in all of which the diffusion term, $\sigma_P(r,t,T)$, is independent of the interest rate and can be written as $\sigma_P(t,T)$.

Then, we can derive the value of T_n-maturity debt is:

$$\begin{aligned} D(0,T_n) &= E_0^Q[\Lambda(0,T_n)\min\{X_n, A(T_n)\}] \\ &= P(0,T_n)E_0^{F_n}[\min\{X_n, A(T_n)\}] \quad n > 1 \\ &= P(0,T_n)X_n N_n^- + A(0)(N_{n-1}^+ - N_n^+) \end{aligned}$$
$$(75.18)$$

where

$$N_j^\pm = N_j(h_1^\pm(X_1), \cdots, h_j^\pm(X_j); \rho_{ij})$$
$$\rho_{ij} = \sqrt{T_i/T_j}, \quad i < j$$

$$h_i^\pm(X_i) = \dfrac{\ln\dfrac{A(0)}{P(0,T_i)X_i} \pm \frac{1}{2}v^2(0,T_i)}{v(0,T_i)}$$

$$v^2(0,T_i) = \int_0^{T_i} \sigma_A^2 + \sigma_P^2(u,T_i) - 2\rho_{Ar}\sigma_A\sigma_P(u,T_i)du$$

where ρ_{ij} represents the auto-correlation between $\ln A(T_i)$ and $\ln A(T_j)$ which is $\sqrt{T_i/T_j}$ for $T_i < T_j$. The derivation of (75.18) is given in an appendix. In (75.18), $N_j(\cdots)$ is a

j-dimensional cumulative normal probability.[11] The derivation of (75.18) is given in an appendix that both N_n^+ and N_n^- are probabilities being in the money, only defined in different probability measures.

Equation 75.18 has an interesting interpretation. Note that N_n^- is the survival probability from now till T_n and $N_{n-1}^- - N_n^-$ (or $N_{n-1}^+ - N_n^+$ under a different measure) is the *unconditional* default probability between T_{n-1} and T_n. In other words, (75.18) implies that if default does not happen (with probability N_n^-), the bond receives X_n. If default does happen, it receives $A(T_n)$. Note that any prior default (default before T_{n-1}) should pay no recovery for such a bond since it is the most junior bond and the last to receive recovery. And this recovery is multiplied by the default probability and discounted to be $A(0)(N_{n-1}^+ - N_n^+)$ today.

It should be noted that (75.18) is not a closed form result unless $v(0,T_i)$ has a closed form expression. Rabinovitch (1989) shows that a closed form expression for $v(0,T_i)$ exists if the term structure model follows Vasicek (1977) and does not exist if it follows Cox-Ingersoll-Ross (1985). We restate the closed form result of Rabinovitch in an appendix.

The T_n-maturity coupon bond that pays hc_n as coupons can be regarded as the total debt of the firm if $X_i = hc_n$ for $i = 1, \ldots, n-1$ and $X_n = 1 + hc_n$ where h is defined in (75.18), as the time period length:

$$\begin{aligned} V_{EM}(0,T_n) &= \sum_{i=1}^n D(0,T_i) \\ &= A(0)[1 - N_n^+] + \sum_{i=1}^n P(0,T_i)X_i N_i^- \\ &= R_n(0) + \sum_{i=1}^n P(0,T_i)Q(0,T_i)hc_n \end{aligned}$$
$$(75.19)$$

where the forward survival probability notation $Q(t,T_i)$ replaces multi-variate normal probabilities N_i^-. Equation 75.19 resembles (75.8) remarkably. The only difference is the recovery assumption. Note that the first term $1 - N_n^+$ represents the total unconditional default probability (under a different measure). While (75.19) is much simpler than (75.8), it requires the knowledge the underlying asset. But this problem can be easily resolved by a recursive equation:

$$\begin{aligned} &\dfrac{V_{EM}(0,T_n) - \sum_{i=1}^n P(0,T_i)Q(0,T_i)c_n - P(0,T_n)Q(0,T_n)}{1 - N_n^+} \\ &= \dfrac{V_{EM}(0,T_{n-1}) - \sum_{i=1}^{n-1} P(0,T_i)Q(0,T_i)c_{n-1} - P(0,T_{n-1})Q(0,T_{n-1})}{1 - N_{n-1}^+} \end{aligned}$$
$$(75.20)$$

---

[11] Equations 75.17 and 75.18 are consistent with Vasicek (1977), but not Cox et al. (1985).

Under the par bond assumption, $V(0, T_n) = 1$ and $y_n = c_n$ and hence (75.20) can be written as:

$$\frac{1 - \sum_{i=1}^{n} P(0,T_i)Q(0,T_i)hy_n - P(0,T_n)Q(0,T_n)}{1 - \sum_{i=1}^{n-1} P(0,T_i)Q(0,T_i)hy_{n-1} - P(0,T_{n-1})Q(0,T_{n-1})}$$
$$= \frac{1 - N_n^+}{1 - N_{n-1}^+} = \theta_n$$

(75.21)

Note the following identity:

$$1 = \sum_{i=1}^{n} P(0,T_i)Q(0,T_i)hc_n^0 + P(0,T_n)Q(0,T_n) \quad (75.22)$$

where $c_n^0 = y_n^0$ is the coupon of a zero-recovery risky par bond. Hence, (75.17) can be simplified as follows:

$$\frac{\sum_{i=1}^{n} P(0,T_i)Q(0,T_i)(y_n^0 - y_n)}{\sum_{i=1}^{n-1} P(0,T_i)Q(0,T_i)(y_{n-1}^0 - y_{n-1})} = \theta_n \quad (75.23)$$

The extended Merton model is usually categorized as a structural model, because of its endogenous recovery assumption and the use of asset value. However, default is defined as the asset value crossing an external barrier. This could cause negative equity value. To see that, we can look at the payoffs at time T_{n-1}:

$A(T_{n-1}) > X_{n-1}$

$$\Rightarrow \begin{cases} D(T_{n-1}, T_{n-1}) = X_{n-1} \\ D(T_{n-1}, T_n) = P(T_{n-1}, T_n)E_{n-1}^F[\min\{A(T_n), X_n\}] \\ E(T_{n-1}) = P(T_{n-1}, T_n)E_{n-1}^F[\max\{A(T_n) - X_n, 0\}] - X_{n-1} \end{cases}$$

$A(T_{n-1}) \leq X_{n-1}$

$$\Rightarrow \begin{cases} D(T_{n-1}, T_{n-1}) = A(T_{n-1}) \\ D(T_{n-1}, T_n) = 0 \\ E(T_{n-1}) = 0 \end{cases}$$

When $A(T_{n-1})$ is small, there is no guarantee that the equity value, $E(T_{n-1})$, can exceed X_{n-1} since X_{n-1} can be arbitrary. To keep the continuity assumption of the asset value at time T_{n-1}, we need to issue new equity when it is negative. In other words, we allow the company to raise new equity when it is already in bankruptcy. Clearly this is not possible in reality. There are three approaches to avoid such a problem. The first is to set the default boundary at equity value, not asset value, equal to X_{n-1}. This is the Geske-Johnson model that we will discuss in the next sub-section. Second, we should treat the underlying asset as an

unobservable state variable and specify recover value separately (e.g. Longstaff and Schwartz (1995) and Zhou (2001)). But doing so effectively transforms the structural model into reduced form in that both defaults and recovery are exogenously specified. It differs from the reduce form approach only by different default process, one assumes a Poisson process and the other assumes a diffusion variable crossing a barrier. Third, we can simplify the debt structure so that an endogenous barrier can be solved (e.g. Leland, 1994; Leland and Toft, 1996).

75.3.4 The Geske-Johnson Model

A true structural model is Geske (1977) and Geske and Johnson (1984) in which internal strikes are solved to guarantee positive equity value. We extend the Geske-Johnson model of an n period risky debt to incorporate random interest rates.[12, 13] The T_n-maturity zero coupon bond can be written as follows.

$$D(0, T_n) = \sum_{i=1}^{n} P(0, T_i)X_i[\Pi_i^-(K_{1n}, \cdots, K_{in})$$
$$- \Pi_i^-(K_{1n-1}, \cdots, K_{in-1})]$$
$$+ A(0)[\Pi_{n-1}^+(K_{1n-1}, \cdots, K_{n-1n-1})$$
$$- \Pi_n^+(K_{1n}, \cdots, K_{nn})] \quad (75.24)$$

where[14]

$$\Pi_i^\pm(K_{1j}, K_{2j}, \cdots, K_{ij}) = \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} N_i(h_1^\pm(K_{1j}(r)), h_2^\pm(K_{2j}(r)),$$
$$\cdots, h_i^\pm(K_{ij}(r)))\varphi(r(T_1),$$
$$r(T_2), \cdots, r(T_i))$$
$$dr(T_1)dr(T_2), \cdots, dr(T_i)$$

for $n \geq j \geq i$ where φ is the joint density function of various interest rate levels observed at different times under the forward measure. Note that $h_j^\pm(K_{ij})$, for $i < j$, is to plug into (75.18) K_{ij} for the strike and K_{ij} is the internal solution to:

---

[12] The formulas provided by Geske (1977) are incorrect and corrected by Geske and Johnson (1984). However, Geske and Johnson only present formulas for $n = 2$. Here, we generalize their formulas to an arbitrary n.

[13] Later on, for calibration, we also augment the model to include non-constant volatility.

[14] Note that the implementation of (75.24) does not need multi-variate integrals. The easiest way to implement it is to construct a bi-variate lattice. Eom et al. (2002), for example, use a one-dimension binomial model to implement the deterministic Geske-Johnson model.

$$A(T_i) = \sum_{k=i}^{j} D(T_i, T_k) + X_i$$

which is a function of the interest rate at time T_i, and $K_{ii} = X_i$. All strikes are solved internally. Note that since interest rates are random, the internally solved strike, K_{ij}, is a function of r under the forward measure. If interest rates are deterministic, then $\Pi_i^{\pm} = N_i(\cdots)$ the standard multi-variate normal probability function. If we further assume that default points are equal to cash obligations, i.e. $K_{ij} = X_i$ for all j, then $\Pi_i^{\pm} = N_i^{\pm}$ defined in (75.18).

Although each bond is computed by a complicated formula, the coupon bond is not:

$$
\begin{aligned}
V_{\text{GJ}}(0, T_n) &= \sum_{i=1}^{n} D(0, T_i) \\
&= A(0)[1 - \Pi_n^{+}(K_{1n}, K_{2n}, \cdots, K_{nn})] \\
&\quad + \sum_{i=1}^{n} P(0, T_i) X_i \Pi_i^{-}(K_{1n}, \cdots, K_{in}) \\
&= R_n(0) + \sum_{i=1}^{n} P(0, T_i) Q(0, T_i) hc_n \\
&\quad + P(0, T_n) Q(0, T_n)
\end{aligned}
\tag{75.25}
$$

where $X_i = hc_n$ for $i < n$ and $X_i = 1 + c_n h$ for $i = n$. This equation is extremely similar to (75.19) except that the probabilities are defined differently due to different strikes. Hence, by observation, the recovery must be $R_n(0) = A(0)[1 - \Pi_n^{+}(K_{1n}, K_{2n}, \cdots, K_{nn})]$. It is interesting to see that the Geske-Johnson model satisfies the condition $Q(0, T_i) > Q(0, T_{i+1})$

Note again that $\Pi_n^{-}(K_{1n}, K_{2n}, \cdots, K_{nn})$ is the total survival probability (under the forward measure) because the asset value, $A(t)$ needs to stay above its default boundaries, K_{ij} at all times. Hence, the total (cumulative) default probability is $[1 - \Pi_n^{1}(K_{1n}, K_{2n}, \cdots, K_{nn})]$. To see it, we know that the total default probability can be derived directly from summing the default probability of each period:

$$
\int_0^{K_{1n}} \varphi(A_1) dA_1 + \int_{K_{1n}}^{\infty} \int_0^{K_{2n}} \varphi(A_1, A_2) dA_2 dA_1 + \cdots
$$

$$
+ \int_{K_{1n}}^{\infty} \cdots \int_{K_{n-1n}}^{\infty} \int_0^{K_{nn}} \varphi(A_1, \cdots, A_n) dA_n \cdots dA_1
$$

$$
= 1 - \int_{K_{1n}}^{\infty} \cdots \int_{K_{n-1n}}^{\infty} \int_{K_{nn}}^{\infty} \varphi(A_1, \cdots, A_n) dA_n \cdots dA_1
$$

$$
= 1 - \Pi_n^{-}(K_{1n}, \cdots K_{nn})
\tag{75.26}
$$

where $A_i = A(T_i)$ is a short-hand notation. This is analogous to $\int_0^T -dQ(t) = 1 - Q(T)$. The recovery is to consider the cash amount received upon default:

$$
P(0, T_1) \int_0^{K_{1n}} A_1 \varphi(A_1) dA_1 + P(0, T_2) \int_{K_{1n}}^{\infty} \int_0^{K_{2n}} A_2 \varphi(A_1, A_2) dA_2 dA_1
$$

$$
+ \cdots + P(0, T_n) \int_{K_{1n}}^{\infty} \cdots \int_{K_{n-1n}}^{\infty} \int_0^{K_{nn}} A_n \varphi(A_1, \cdots, A_n) dA_n \cdots dA_1
$$

$$
= A_0 \left[1 - \int_{K_{1n}}^{\infty} \cdots \int_{K_{n-1n}}^{\infty} \int_{K_{nn}}^{\infty} \varphi^{+}(A_1, \cdots, A_n) dA_n \cdots dA_1 \right]
$$

$$
= A_0 [1 - \Pi_n^{+}(K_{1n}, \cdots K_{nn})]
\tag{75.27}
$$

The change of measure can be found in an appendix.

In this unified framework, we can see that the difference in the Geske-Johnson model differs from Jarrow-Turnbull model is that Jarrow and Turnbull assume a fixed recovery value at maturity while Geske and Johnson assume a fixed recovery value at current time.

75.4 Calibration and Model Comparison

In this section, we demonstrate how different models can calibrate to the same market data and imply different parameter values. Equation 75.8 represents a general formula for all risky bond pricing models, reduced form and structural models included. It is seen that the difference only lies in the recovery assumption: recovery of the face value yields the Jarrow-Turnbull model; recovery of the market value yields the Duffie-Singleton model, and recovery of the asset value yields the Geske-Johnson model.

We shall first use a two-period model as an example to demonstrate the computational details. Then we provide analysis in a multi-period setting. The Vasicek model (1977) for the risk free term structure of interest rates is considered.

75.4.1 A Two-Period Example

We need three pieces of information to complete the calibration: risk free zero yield curve, a set of risky bond prices, and a recovery assumption. In the case of structural models, the recovery assumption is replaced by the volatility curve for the set of bond prices.

To demonstrate the calibration procedures for both reduced form and structural models, we use a two-period example. The following table describes the base case:

Time	1	2
Coupon	10	10
Face	100	100
Bond price	100	100
Yield curve	5%	5%

The Jarrow-Turnbull model can be calibrated as follows. From (75.11), we obtain the 1 year bond formula:

$$V_{\text{JT}}(0,1) = P(0,1)[Q(0,1)(1+c_1) + (1-Q(0,1))w_1]$$

We assume a fixed recovery rate of 0.4 of the principal and accrued interest. In this 1-year example, the recovery amount is $44 if default occurs. Given coupon $c_1 = \$10/\$100 = 10\%$ and 1-year discount $P(0,1) = e^{-5\%} = 0.9512$, we can solve for the survival probability to be $Q(0,1) = 0.9262$. Again, from (75.11), for the 2-year bond:

$$\begin{aligned}V_{\text{JT}}(0,2) &= P(0,1)Q(0,1)c_2 + P(0,2)Q(0,2)(1+c_2) \\ &\quad + P(0,1)[1-Q(0,1)]w_2 + P(0,2)[Q(0,1) \\ &\quad - Q(0,2)]w_2\end{aligned}$$

With the knowledge of $Q(0,1)$, together with $P(0,2) = e^{-10\%} = 0.9048$, we can then solve for the second period survival probability to be $Q(0,2) = 0.8578$.

The Duffie-Singleton model can be calibrated as follows. From (75.13), we have:

$$V_{\text{DS}}(0,1) = P(0,1)Q^*(0,1)(1+c_1)$$

for the 1-year bond and

$$V_{\text{DS}}(0,2) = P(0,1)Q^*(0,1)c_2 + P(0,2)Q^*(0,2)(1+c_2)$$

for the 2-year bond. Hence, we solve for $Q^*(0,1) = 0.9557$ and $Q^*(0,2) = 0.9134$. From (75.14), we know that $Q^*(0,t) > Q(0,t)$ always due to non-negative recovery. By assuming a recovery rate of 0.4, we get $Q(0,1) = 0.8929$ and $Q(0,2) = 0.7973$, which are both lower than the survival probabilities calculated by the Jarrow-Turnbull model. Note that in both models, the recovery present values for 1 and 2-year bonds are 3.09 and 5.81 for Jarrow-Turnbull and 6.57 and 12.15 for Duffie-Singleton, respectively. It is seen that the recovery amounts for Duffie-Singleton are higher, and hence to maintain the same the bond values, the survival (default) probabilities of Duffie-Singleton have to be lower (higher) to balance it out.

In both the Jarrow-Turnbull model and the Duffie-Singleton model, given that there is no other random factor other than the interest rate, there is no need to identify a specific term structure model, given that survival and default probabilities are computed under the forward measure.

However, in the Geske-Johnson model, in addition to random interest rates, there is a random "asset price" state variable. As a result, a specific term structure model needs to be specified in order to carry out survival and default probabilities.

To simplify the calculation and without any loss of generality, we assume a deterministic yield curve in this section. The Vasicek term structure model is assumed in the next sub-section. In the Geske-Johnson model, the recovery amount is random and endogenous. Under deterministic interest rates, the one-period Geske-Johnson model is a Black-Scholes-Merton solution:

$$\begin{aligned}V_{\text{GJ}}(0,1) &= D(0,1) = P(0,1)X_1N(h_1^-(X_1)) \\ &\quad + A(0)[1 - N(h_1^+(X_1))]\end{aligned}\tag{75.28}$$

where $h_1^{\pm}$ is defined in (75.18). Since interest rates are non-stochastic, $P(0,1) = \Lambda(0,1)$. Equation 75.28 is identical to (75.18) when $\sigma_P = 0$ and $T_n = T_1 = 1$. For the 2-year bond, i.e. $T_n = T_2 = 2$ and $T_1 = 1$, we have two zero bond components:

$$D(0,1) = P(0,1)X_1N(h_1^-(X_1)) + A(0)[1 - N(h_1^+(X_1))]\tag{75.29}$$

and

$$\begin{aligned}D(0,2) &= P(0,1)X_1[N_1(h_1^-(K_{12})) - N_1(h_1^-(X_1))] \\ &\quad + P(0,2)X_2N_2(h_1^-(K_{12}), h_2^-(X_2); \sqrt{1/2}) \\ &\quad + A(0)\left[N_1(h_1^+(X_1)) - N_2(h_1^+(K_{12}), h_2^+(X_2); \sqrt{1/2})\right]\end{aligned}\tag{75.30}$$

where $h_i^{\pm}$ for $i = 1, 2$ is defined in (75.18), $X_1 = c_2$, $X_2 = 1 + c_2$. Recall that K_{12} is the solution to $A(1) = D \times (1,2) + X_1$ where $D(1,2)$ is a bond price at $t = 1$. Finally, the 2-year coupon bond value is the sum of (75.29) and (75.30):

$$\begin{aligned}V_{\text{GJ}}(0,2) &= D(0,1) + D(0,2) \\ &= P(0,1)X_1N(h_1^-(X_1)) + P(0,2)X_2N_2(h_1^-(K_{12}), h_2^-(X_2)) \\ &\quad + A_0\left[1 - N_2(h_1^+(K_{12}), h_2^+(X_2); \sqrt{1/2})\right]\end{aligned}\tag{75.31}$$

In the equation, we need to evaluate three probabilities. The first one is $N(h_1^-)$ which has already been evaluated. The second one is a bivariate normal probability with two separate strikes, K_{12} that has to be internally solved and X_2 that is the face and coupon value at maturity.

Note that X_1 is the first cash flow of the company, hence $X_1 = 10 + 110 = 120$. The value of $D(0,1)$ hence contains the cash flow of the first bond and the coupon amount of the second bond. Here, we assume that the split of $D(0,1)$ is proportional. That is the value of the 1-year bond is $\frac{110}{120}D(0,1)$, and the value of the 2-year bond is $\frac{10}{120}D(0,1) + D(0,2)$.

In the original Geske-Johnson model, the volatility is assumed flat (as in Black-Scholes, 1973). Unfortunately under this condition, the calibration of the second bond becomes impossible. Hence, we extend the model to include a volatility curve, i.e. $v(0,2)^2 = v(0,1)^2 + v(1,2)^2$. This flexibility allows us to calibrate the model to the 2-year bond price. The results are $A(0) = 2351.65$, $v(0,1) = 1.5$, and $v(1,2) = 0.69$. Under such results, the survival probabilities are $Q(0,1) = N_1^-(K_{12}) = 0.9426$ and $Q(0,2) = N_2^-(K_{12}, X_2) = 0.8592$ respectively. And the recovery values for the two bonds are computed by subtracting the coupon value from the corresponding discount debt value. For example, $D(0,1) = 109.09$ which is split into two parts – the 1-year bond of \$100 and the coupon of the 2-year bond of \$9.09. The 1-year bond has a coupon portion of $110 \times Q \times (0,1) \times P(0,1) = 110 \times 0.9426 \times 0.9512 = 98.63$, and hence has a recovery value of $100 - 98.63 = 1.37$. A similar calculation gives the recovery value of the 2-year bond as 5.52.[15]

For easy comparison, we put together all the numbers in the following table. We observe that the Duffie-Singleton (DS) model has the lowest survival probabilities and therefore should have the highest recovery values, due to the fact that they both contribute positively to the bond price. The Geske-Johnson (GJ) model has the highest survival probabilities and lowest recovery values. The Jarrow-Turnbull (JT) model is in between. Since the bond price is traded at par, higher survival probabilities need to be balanced by lower recovery values.

	JT	DS	GJ
$Q(0,1)$	0.9262	0.8929	0.9426
$Q(0,2)$	0.8578	0.7923	0.8592
Total recovery value (i.e. $R(0)$)	8.90	18.68	6.89
Recovery of first bond	3.09	6.53	1.37
Recovery of second bond	5.81	12.15	5.52

75.4.2 Multi-period Analysis

In this section, we examine the multi-period behavior of reduced form models, namely Jarrow-Turnbull and Duffie-Singleton and the structural model of Geske-Johnson. We examine the default and recovery implication under an n-period setting. We also incorporate stochastic interest rates

---

[15] Note that the total recovery value needs to be 6.89 by (75.31).

in our analysis. We replace the interest rate process in (75.16) by the following Ornstein-Uhlenbeck process:

$$dr(t) = \alpha\left(\mu - \frac{\delta q}{\alpha} - r(t)\right)dt + \delta dW_r^Q(t) \qquad (75.32)$$

where the parameter values are given for flat (constant) and upward sloping yield curves as follows

Vasicek model parameters		
	Flat	Upward
α (reverting speed)	∞	0.40
μ (reverting level)	0.05	0.08
δ (volatility)	0.00	0.05
q (mkt. price of risk)	0.00	-0.10
$r(0)$ (initial rate)	0.05	0.05

We first examine flat yield curve. Then we use the upward sloping parameter values to construct the Vasicek model. The two sets of results are similar and we shall present the flat yield curve result and the other one is available upon request.

We first examine the case of extremely low coupons. This is the case where we can see the fundamental difference between the structural model of Geske-Johnson and the reduced form models of Jarrow-Turnbull and Duffie-Singleton. Note that the Jarrow-Turnbull model is (75.11) and the Duffie-Singleton model is (75.13) and (75.14), both with $c_n = 0$. The Geske-Johnson model is (75.25) with $X_i = 0$ for $i < n$. In all the models, the zero coupon bond price, $P(t,T)$, should follow the Vasicek model (formula given in an appendix.) The face value of debt is 110. We run the Geske-Johnson model with an asset value of $A(0) = 184$ and various volatility levels: 0.4, 0.6, 1.0, and 1.6. The results computed are summarized as follows.

GJ Model				
Volatility	0.4	0.6	1.0	1.6
Equity value	169.25	177.92	183.49	183.94
Debt value	14.74	6.08	0.51	0.06
Recovery	4.06	2.08	0.19	0.00
JT Model				
Recovery rate	3.69%	1.89%	0.17%	0.00%
Intensity	1.79%	4.85%	13.19%	20.00%

As the volatility goes up, the equity value in the Geske-Johnson model goes up (i.e. call option value goes up.) Since the asset value is fixed at 184, the debt value goes down. The survival probability curves under various volatility scenarios of the Geske-Johnson model are plotted in Figure 75.1; and the default probability curves (unconditional, i.e. $Q(T_{i-1}) - Q(T_i)$) are plotted in Figure 75.2. We observe several results. First, as the risk of default becomes eminent (i.e. high volatility and low debt value), the likelihood of default shifts from far term (peak at year 30 for volatility $= 0.4$) to near term

**Survival Probability Plot
under various asset volatility levels**
Note: Figure 1 illustrates the survival probability curves under various asset volatility scenarios of the
        30-year zero coupon bond under the Geske-Johnson model. The Asset value is set to be $184.
        The bond has no coupon and a face value of $110. The yield curve is flat at 5%

Fig. 75.1 The GJ model: zero coupon bond (Note: Figure 75.1 illustrates the survival probability curves under various asset volatility scenarios of the 30-year zero coupon bond under the Geske-Johnson

model. The asset value is set to be $184. The bond has no coupon and a face value of $110. The yield curve is flat at 5 %)

Fig. 75.2 The GJ model: zero coupon bond (Note: Figure 75.2 illustrates the default probability curve. All parameters are identical to those in Figure 75.1)

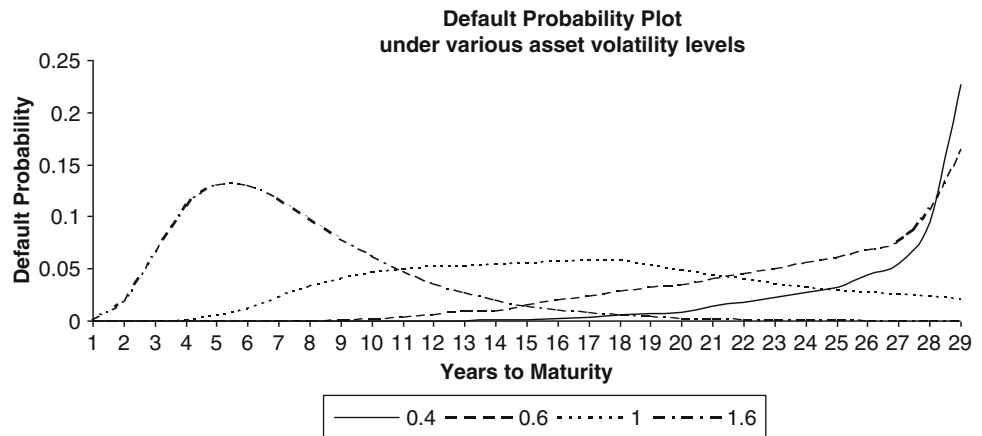
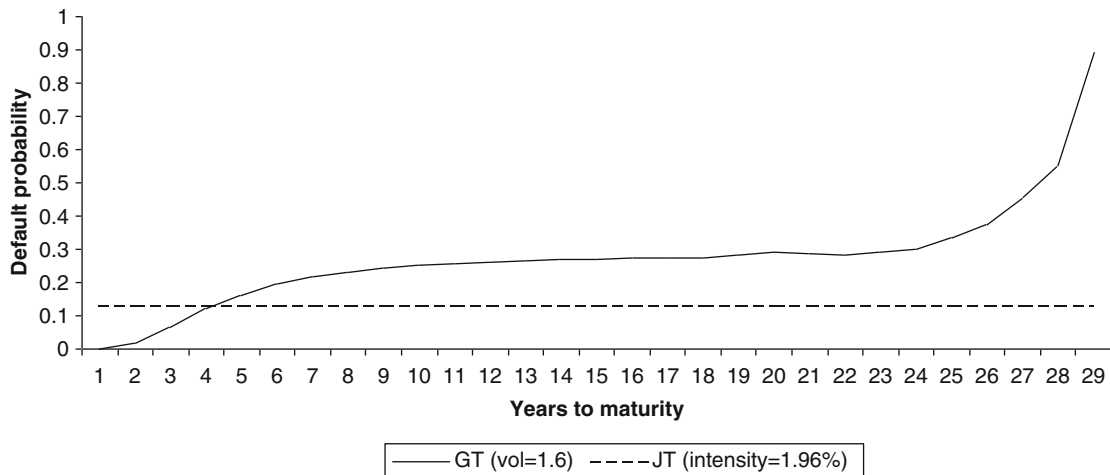
under various asset volatility levels**


Note: Figure 1a illustrates the default probability curve. All parameters are identical to those in
        Figure 1.

(peak at year 5 for volatility = 1.6). Second, it is seen that the asset volatility has a huge impact on the shape of the survival probability curve. The Geske-Johnson model is able to generate humped default probability curve, often observed empirically. Third, these differently shaped probability curves are generated by one single debt, something not possible reduced form models. Both the Jarrow-Turnbull and Duffie-Single models cannot generate such probability curves with one single bond, due to the lack of information of intermediate cash flows. Corresponding to the recovery amounts under the Geske-Johnson model, we set the fixed recovery rate of the Jarrow-Turnbull model as shown in the

above table. Given that one bond can only imply one intensity parameter value, we set it (under each scenario) so that the zero coupon bond price generated by the Geske-Johnson model is matched. As shown in the above table, the intensity rate goes from 1.79% per annum to 20% per annum. Note that flat intensity value is equivalent to a flat *conditional* default probability curve. To visualize the difference this flat conditional default probability curve of the Jarrow-Turnbull model with the non-flat curve generated by the Geske-Johnson model, we plot in Figure 75.3 the case of volatility = 1.6. The conditional default probabilities are calculated as $\frac{Q(T_{i-1}) - Q(T_i)}{Q(T_{i-1})}$.

Conditional Forward Default Probability Curves


Note: Figure 1b illustrates the default probability curves under GJ and JT models for the volatility level
        of 1.6. All parameters are identical to those in Figure 1.

Fig. 75.3 Comparison of GJ and JT models: zero coupon bond (Note: Figure 75.3 illustrates the default probability curves under GJ and JT models for the volatility level of 1.6. All parameters are identical to those in Figure 75.1)

Survival Probability Plot
GJ model at various volatility levels
Note: Figure 2 illustrates the survival probability curves under various asset volatility scenarios of the
        30-year Geske-Johnson model. The Asset values are 123, 290, 15,000 for volatility levels of 0.4,
        0.6, and 1.0 repsectively. The bond has a coupon of $10 and price of par.

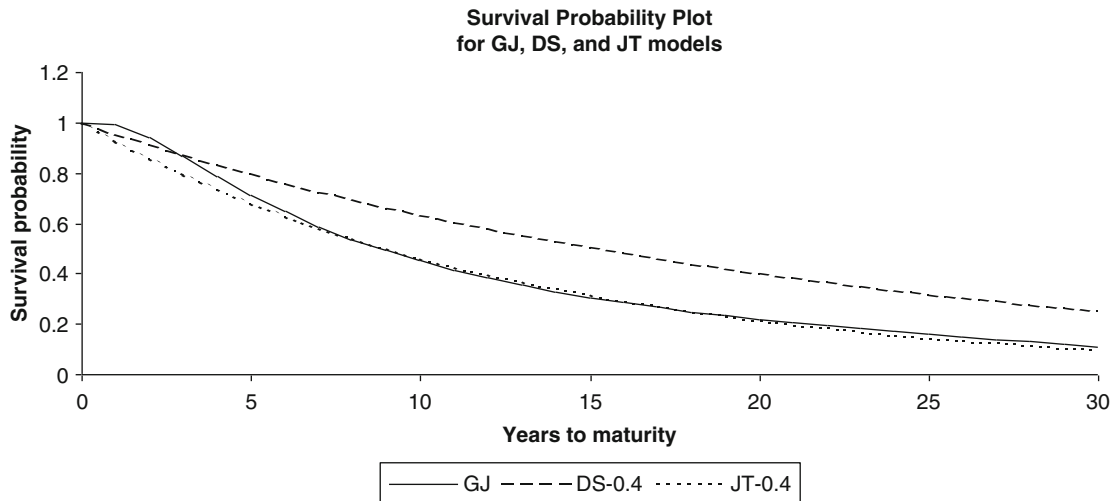
Fig. 75.4 The GJ model: 10 % coupon bond (Note: Figure 75.4 illustrates the survival probability curves under various asset volatility scenarios of the 30-year Geske-Johnson model. The asset values are 123, 290, 15,000 for volatility levels of 0.4, 0.6, and 1.0 respectively. The bond has a coupon of $10 and price of par)

Our next analysis is to keep bond value fixed, so that we can examine the default probability curve with the risk of the bond controlled. We assume that the company issues only one coupon bond at 10%. At the volatility level of 0.4, the asset value is $123, at 0.6, it is $290, at 1.0, it is $15,000. Figures 75.4 and 75.5 demonstrate the Geske-Johnson model for various volatility levels but keep the bond at par. We can see that for the same par bond, the default and survival probability curves are drastically different as the asset/volatility combination changes. This is a feature not captured by either the Duffie-Singleton or the Jarrow-Turnbull model.

To compare to the Jarrow-Turnbull and Duffie-Turnbull models, we keep the case where the volatility level is 0.6 and asset value is 290. The recover rates of both Jarrow-Turnbull and Duffie-Singleton models are assumed to be 0.4.

Default Probability Plot
GJ model at various volatility levels
Note: Figure 2a illustrates the default probability curves under various asset volatility scenarios of the 30-year Geske-Johnson model. The Asset values are 123, 290, 15,000 for volatility levels of 0.4, 0.6, and 1.0 repsectively. The bond has a coupon of $10 and price of par. All parameters are identical to those in Figure 2.

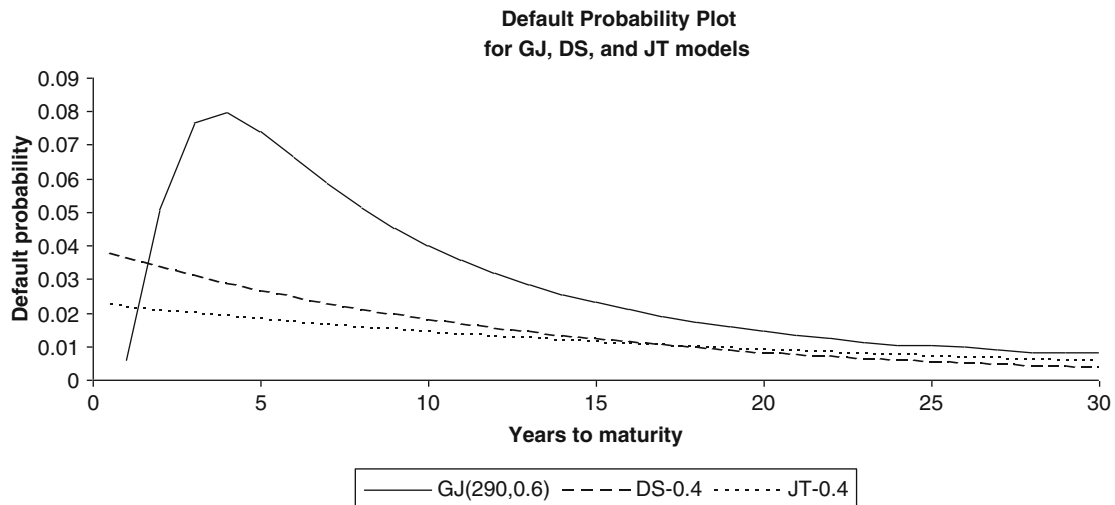
Fig. 75.5 The GJ model: 10 % coupon bond (Note: Figure 75.5 illustrates the default probability curves under various asset volatility scenarios of the 30-year Geske-Johnson model. The asset values are 123, 290, 15,000 for volatility levels of 0.4, 0.6, and 1.0 respectively. The bond has a coupon of $10 and price of par. All parameters are identical to those in Figure 75.4)

Survival Probability Plot
for GJ, DS, and JT models


Note: Figure 3 illustrates the survival probability curves under the 30-year Geske-Johnson, Duffie-Singleton with 0.4 recovery ratio, and Jarrow-Turnbull with 0.4 recovery ratio models. The Asset value is set to be $290 and volatility 0.6 so that the bond is priced at par. The bond has $10 coupon and a face value of $110.

Fig. 75.6 Comparison of the GJ, DS and JT models: par coupon bond (Note: Figure 75.6 illustrates the survival probability curves under the 30-year Geske-Johnson, Duffie-Singleton with 0.4 recovery ratio, and Jarrow-Turnbull with 0.4 recovery ratio models. The asset value is set to be $290 and volatility 0.6 so that the bond is priced at par. The bond has $10 coupon and a face value of $110)

Figures 75.6 and 75.7 show the survival and default probability curves of the three models. The flat conditional forward default probability for the Jarrow-Turnbull model is solved to be 7.60% (or equivalently the intensity rate is 7.74%.) The conditional forward default probabilities for the Duffie-Singleton model are certainly non-constant. The "recovery-adjusted" continuously compounded discount rate is 9.52%. From the survival probability curves

**Default Probability Plot
for GJ, DS, and JT models**


Note: Figure 3a illustrates that under a 10% coupon bond, the Geske-Johnson model can generate
desired default probability curve. All parameters are identical to those in Figure 3.

Fig. 75.7 Comparison of the GJ, DS and JT models: par coupon bond (Note: Figure 75.7 illustrates that under a 10 % coupon bond, the Geske-Johnson model can generate desired default probability curve. All parameters are identical to those in Figure 75.6)

(Figure 75.6), it is seen that the Geske-Johnson and Jarrow-Turnbull models can be close. But the default probability curves (Figure 75.7) demonstrate that the default pattern can be quite different.

Conclusion

In this paper, we provide a general framework that brings consistency between the reduced form and structural models. The structural models we consider in this paper is not those of the "barrier-type" that assumes exogenous barriers but the Geske-Johnson model that allows the default points (strike price) to be endogenously computed. We show that the "true structural" model of Geske-Johnson can be simplified to barrier-type (extended Merton) if the endogenous default points are not internally solved for but exogenously given.

In a discrete time binomial framework, we show that any set of risky cash flows and recovery can be priced by a simple formula. This formula is same for both structural and reduced form models. This formula allows us to compare various models because they only differ in the recovery computation. Different recovery assumptions result in different survival and default probabilities. In calibration, the differences in recovery amounts and in probabilities balance each other out, as we demonstrate, because each model price is made to match the market price. However, these different recovery values and probabilities should result in large differences in derivatives prices. We demonstrate that large differences

exist even for the simplest credit derivative contract – credit default swaps.

Finally, In order to compare the "true structural" Geske-Johnson model with the reduced form models represented by Jarrow and Turnbull (1995) and Duffie and Singleton (1997, 1999), we extend the Geske-Johnson model to incorporate random interest rates and a non-flat volatility curve. In a series of appendices, we demonstrate how to implement the Geske-Johnson model with random interest rates and a volatility curve.

Appendix: Derivation of (75.18)

We shall derive (75.18) by induction. A T_1-maturity zero coupon bond with a barrier X_1 is:

$$
\begin{aligned}
D(0, T_1) &= E_0^Q\left[e^{-\int_0^{T_1} r(u)du} \min\{A(T_1), X_1\}\right] \\
&= P(0, T_1)E_0^{F_1}[\min\{A(T_1), X_1\}] \\
&= A(0)[1 - N(h_1^+(X_1))] + P(0, T_1)X_1 N(h_1^-(X_1))
\end{aligned}
\tag{75.33}
$$

where $h_1^{\pm}(X_1)$ is defined in the text. A T_2-maturity zero coupon bond with a barrier X_2 has the following value at T_1:

$$
\begin{cases}
E_{T_1}^Q\left[e^{-\int_{T_1}^{T_2} r(u)du} \min\{A(T_2), X_2\}\right] & A(T_1) > X_1 \\
0 & A(T_1) \leq X_1
\end{cases}
\tag{75.34}
$$

Hence, it has the following value today:

$$D(0,T_2) = E_0^Q\left[e^{-\int_0^{T_1} r(u)du} E_{T_1}^Q\left[e^{-\int_{T_1}^{T_2} r(u)du}\min\{A(T_2),X_2\}\right]\right.$$

$$\left. I_{\{A(T_1)>X_1\}}\right]$$

$$= E_0^Q\left[E_{T_1}^Q\left[e^{-\int_0^{T_2} r(u)du}\left(A(T_2)I_{\{A(T_2)<X_2\}}\right.\right.\right.$$

$$\left.\left.\left. + X_2 I_{\{A(T_2)>X_2\}}\right)\right]I_{\{A(T_1)>X_1\}}\right]$$

$$= P(0,T_2)E_0^{F_n}\left[A(T_2)I_{\{A(T_2)<X_2\wedge A(T_1)>X_1\}}\right.$$

$$\left. + X_2 I_{\{A(T_2)>X_2\wedge A(T_1)>X_1\}}\right]$$

$$= P(0,T_2)E_0^{F_n}\left[A(T_2)\left(I_{\{A(T_1)>X_1\}} - I_{\{A(T_2)>X_2\wedge A(T_1)>X_1\}}\right)\right.$$

$$\left. + X_2 I_{\{A(T_2)>X_2\wedge A(T_1)>X_1\}}\right]$$

$$= A(0)[N_1^+ - N_2^+] + P(0,2)X_2 N_2^- \tag{75.35}$$

where the second to last line is obtained by appropriately dividing the integration region. Carrying out the expectation using the standard log normal results should yield the result desired. Similar procedure is applied to any arbitrary T_n.

N_n^+ and N_n^-

In this appendix, we show that N_n^+ and N_n^- are both survival probabilities, but under different probability measures. For the ease of composition, we use $N_1^\pm = N(h_1^\pm(X_1))$ where $N(\cdot)$ is a standard univariate normal probability function, as an example. The general case, while tedious algebraically, is straightforward.

To simplify notation, we drop "1" from $h_1^\pm$, X_1, T_1, and measure F_1. Note that:

$$N(h^+) = \frac{P(0,T)}{A(0)}E_0^F[A(T)I_{\{A(T)>X\}}]$$
$$N(h^-) = E_0^F[I_{\{A(T)>X\}}] \tag{75.36}$$

Equation 75.36 can be written as:

$$E_0^F[A(T)I_{\{A(T)>X\}}] = E_0^F[A(T)]E_0^{F*}[I_{\{A(T)>X\}}]$$
$$= \frac{A(0)}{P(0,T)}E_0^{F*}[I_{\{A(T)>X\}}] \tag{75.37}$$

The change of measure from F to F* is done as follows:

$$\frac{dF^*}{dF} = \frac{A(T)}{E_0^F[A(T)]} \tag{75.38}$$

Given that A is a log normal process, we immediately obtain that the above derivative as a change of measure of $\sqrt{\text{var}[\ln(A(T)]}$ under the F measure. In the following, we sketch the basic math of forward measure.

Assume an interest rate process under the Q measure generally as:

$$dr(t) = \alpha(r,t)dt + \sigma(r,t)dW^Q(t) \tag{75.39}$$

Then, by (75.3), we have the Radon-Nykodym derivative defined as follows:

$$\eta(t,T) = \frac{\Lambda(t,T)}{P(t,T)} \tag{75.40}$$

Applying Ito's lemma on the bond price:

$$0 = \ln P(T,T) = \ln P(t,T) + \int_t^T \frac{1}{P(u,T)}$$

$$\left[P_u(u,T)du + P_r(u,T)dr + \frac{1}{2}P_{rr}(u,T)(dr)^2\right]dW^Q(u)$$

$$- \int_t^T \frac{1}{2}\left[\frac{\sigma(r,u)P_r(u,T)}{P(u,T)}\right]^2 du$$

$$= \ln P(t,T) + \int_t^T \frac{1}{P(u,T)}\left[P_u(u,T)du + P_r(u,T)\hat{\mu}(r,u)\right.$$

$$\left. + \frac{1}{2}P_{rr}(u,T)\sigma(r,u)^2\right]du$$

$$+ \int_t^T \frac{1}{P(u,T)}P_r(u,T)\sigma(r,u)dW^Q(u)$$

$$- \int_t^T \frac{1}{2}\left[\frac{\sigma(r,u)P_r(u,T)}{P(u,T)}\right]^2 du$$

$$= \ln P(t,T) + \int_t^T r(u)du + \int_t^T \frac{1}{P(u,T)}P_r(u,T)\sigma(r,u)dW^Q(u)$$

$$- \int_t^T \frac{1}{2}\left[\frac{\sigma(r,u)P_r(u,T)}{P(u,T)}\right]^2 du$$

$$\tag{75.41}$$

Letting:

$$\theta(t,T) = \frac{\sigma(r,t)P_r(t,T)}{P(t,T)} \tag{75.42}$$

and moving the first two terms to the left:

$$-\int_t^T r(u)du - \ln P(t,T) = \int_t^T \theta(u,T)dW^Q(u) - \int_t^T \frac{1}{2}\theta(u,T)^2 du$$

$$\frac{\Lambda(t,T)}{P(t,T)} = \eta(t,T) = \exp\left(\int_t^T \theta(u,T)dW^Q(u) - \int_t^T \frac{1}{2}\theta(u,T)^2 du\right) \tag{75.43}$$

This implies the Girsonav transformation of the following:

$$W^Q(t) = W^{F_T}(t) + \int_t^T \sigma(r,u)\frac{P_r(u,T)}{P(u,T)}du \tag{75.44}$$

The interest rate process under the forward measure henceforth becomes:

$$dr(t) = \left[\alpha(r,t) + \sigma(r,t)^2 \frac{P_r(t,T)}{P(t,T)}\right]dt + \sigma(r,t)dW^{F_T}(t) \tag{75.45}$$

Note that the forward measure derived above is quite general. It does not depend on any specific assumption on the interest rate process. In the following, "random equity and random interest rate", we do need normally distributed interest rates, or there is no solution to option pricing.

$$\begin{bmatrix} \frac{dA(t)}{A(t)} \\ dr(t) \end{bmatrix} = \begin{bmatrix} r(t) \\ \alpha(r,t) \end{bmatrix}dt + \begin{bmatrix} \sigma_A & 0 \\ 0 & \sigma_r(r,t) \end{bmatrix}$$

$$\times \begin{bmatrix} \sqrt{1-\rho^2} & \rho \\ 0 & 1 \end{bmatrix} \times \begin{bmatrix} dW_S^Q(t) \\ dW_r^Q(t) \end{bmatrix} \tag{75.46}$$

Using the forward measure, we get:

$$\begin{bmatrix} \frac{dA(t)}{A(t)} \\ dr(t) \end{bmatrix} = \begin{bmatrix} r(t) + \rho\sigma_A\sigma_r(r,t)\frac{P_r(t,T)}{P(t,T)} \\ \alpha(r,t) + \sigma_r(r,t)^2\frac{P_r(t,T)}{P(t,T)} \end{bmatrix}dt$$

$$+ \begin{bmatrix} \sigma_A & 0 \\ 0 & \sigma_r(r,t) \end{bmatrix} \times \begin{bmatrix} \sqrt{1-\rho^2} & \rho \\ 0 & 1 \end{bmatrix}$$

$$\times \begin{bmatrix} dW_S^Q(t) \\ dW_r^{F_T}(t) \end{bmatrix} \tag{75.47}$$

$$A(T) = A(t)\exp\left(\int_t^T \left[r(u) + \rho\sigma_A\sigma_r(r,t)\frac{P_r(u,T)}{P(u,T)}\right]du \right.$$

$$\left. + \int_t^T \sigma dW^{F_T}(u) - \frac{1}{2}\int_t^T \sigma^2 du\right) \tag{75.48}$$

where

$$dW^{F_T}(t) = \sqrt{1-\rho^2}dW_S^Q(t) + \rho dW_r^{F_T}(t)$$

From the result of Ito's lemma, we can then arrive at the following result:

$$A(T) = \frac{A(t)}{P(t,T)}\exp\left(\int_t^T \left[-\frac{1}{2}\left[\sigma_r(r,t)\frac{P_r(u,T)}{P(u,T)}\right]^2\right.\right.$$

$$\left.+ \rho\sigma_A\sigma_r(r,t)\frac{P_r(u,T)}{P(u,T)} - \frac{1}{2}\sigma^2\right]du.$$

$$\left.- \int_t^T \sigma_r(r,t)\frac{P_r(u,T)}{P(u,T)}dW_r^{F_T}(u) + \int_t^T \sigma_A dW^{F_T}(u)\right) \tag{75.49}$$

Hence,

$$E_t^{F_T}[\ln S(T)] = \ln S(t) - \ln P(t,T) + \frac{1}{2}v(t,T)^2$$

$$\text{var}_t^{F_T}[\ln S(T)] = v(t,T)^2 \tag{75.50}$$

where

$$v(t,T)^2 = \int_t^T \left[\left[\sigma_r(r,t)\frac{P_r(u,T)}{P(u,T)}\right]^2 - 2\rho\sigma_A\sigma_r(r,t)\frac{P_r(u,T)}{P(u,T)} + \sigma_A^2\right]du$$

Derivation of (75.24)

The Geske-Johnson model is usually written as the multivariate normal probability format. As a result, the final solution looks more complex than it really is. Once, we understand the recursive relationship in zero coupon bond formulas, the final result is very straightforward to recognize. Hence, in this appendix, we provide a simple three period example to demonstrate how we can easily derive and streamline the Geske-Johnson model. The rest can be obtained by induction.

For the 1-year zero, it is identical to the Merton-Rabinovitch model:

$$D(0,T_1) = V_{GJ}(0,T_1) = P(0,T_1)K_{11}[N_1(h_1^-(K_{11})) - 0]$$
$$+ A(0)[1 - N_1(h_1^+(K_{11}))]$$
$$= P(0,T_1)K_{11}\Pi_1^-(K_{11}) + A(0)[1 - \Pi_1^+(K_{11})]$$
(75.51)

Note that $K_{11} = X_1$, the first coupon. The second line of the above equation is merely a notation change. The simpler notation allows to more easily label high dimension normal probabilities with different strikes.

For the 2-year zero, we need to solve for an internal solution K_{12} that equates

$$A(T_1) = D(T_1,T_2) + X_1 \tag{75.52}$$

where

$$D(T_1,T_2) = E_{T_1}^Q[\Lambda(T_1,T_2)\min\{A(T_2),X_2\}]$$
$$= P(T_1,T_2)N(d_-) + A(T_1)[1 - N(d_+)] \tag{75.53}$$

and

$$d_\pm = \frac{\ln A(T_1) - \ln P(T_1,T_2) - \ln X_2 \pm \frac{1}{2}v^2(T_1,T_2)}{v(T_1,T_2)}$$
(75.54)

is a Merton-Rabinovitch result again. Note that $v^2(\cdot,\cdot)$ is defined in (75.18). We should note that since $P(T_1,T_2)$ is a function of the interest rate at time T_1, i.e. $r(T_1)$. As a result, K_{12} is also a function of $r(T_1)$. For the convenience of later derivation, we rewrite (75.66) in its original integral form as follows. Also for notational convenience, we shorten the following notation: $D(T_i,T_j) = D_{ij}$, $P(T_i,T_j) = P_{ij}$, $A(T_i) = A_i$ and $r(T_i) = r_i$.

$$D_{12} = \int_{-\infty}^{\infty} \int_{X_2}^{\infty} \Lambda_{12}X_2\varphi(A_2,r_2)dA_2dr_2$$
$$+ \int_{-\infty}^{\infty} \int_{0}^{X_2} \Lambda_{12}A_2\varphi(A_2,r_2)dA_2dr_2 \tag{75.53a}$$

This expression allows us to easily integrate with other integrals. The value of the 2-year zero price at T_1 is:

$$\begin{cases} D_{12} & A_1 > K_{12} \\ A_1 - X_1 & X_1 < A_1 \le K_{12} \\ 0 & A_1 \le X_1 \end{cases} \tag{75.55}$$

To obtain the current value of the 2-year zero, we simply integrate these payoffs at its corresponding region. Note that K_{12} is a function of the interest rate.

$$D(0,2) = \underbrace{\int_{-\infty}^{\infty} \int_{K_{12}}^{\infty} \Lambda_{0,1}E[\Lambda_{1,2}\min\{A_2,F_2\}]\varphi(A_1,r_1)dA_1dr_1}_{\Delta_1}$$
$$+ \underbrace{\int_{-\infty}^{\infty} \int_{X_1}^{K_{12}} \Lambda_{0,1}(A_1 - F_1)\varphi(A_1,r_1)dA_1dr_1}_{\Delta_2}$$
(75.56)

The second term can be shown as:

$$\Delta_2 = \int_{-\infty}^{\infty} \int_{K_{11}}^{\infty} \Lambda_{01}(V_1 - F_1)\varphi(V_1,r_1)dV_1dr_1$$
$$- \int_{-\infty}^{\infty} \int_{K_{12}}^{\infty} \Lambda_{01}(V_1 - F_1)\varphi(V_1,r_1)dV_1dr_1$$
$$= V_0[\Pi_1^+(K_{11}) - \Pi_1^+(K_{12})] - P_{01}X_1[\Pi_1^-(K_{11}) - \Pi_1^-(K_{12})] \tag{75.57}$$

The first term can be valued as:

$$\Delta_1 = \int_{-\infty}^{\infty} \int_{K_{12}}^{\infty} \Lambda_{01}\left[\int_{-\infty}^{\infty}\int_{0}^{K_{22}} \Lambda_{12}A_2\varphi(A_2,r_2|A_1,r_1)dA_2dr_2\right]$$
$$\varphi(A_1,r_1)dA_1dr_1$$
$$+ \int_{-\infty}^{\infty} \int_{K_{12}}^{\infty} \Lambda_{01}\left[\int_{-\infty}^{\infty}\int_{K_{22}}^{\infty} \Lambda_{12}X_2\varphi(A_2,r_2|A_1,r_1)dA_2dr_2\right]$$
$$\varphi(A_1,r_1)dA_1dr_1$$
$$= \int_{-\infty}^{\infty} \int_{K_{12}}^{\infty} \Lambda_{0,1}\left[\int_{-\infty}^{\infty}\int_{0}^{\infty} \Lambda_{12}A_2\varphi(A_2,r_2|A_1,r_1)dA_2dr_2\right]$$
$$\varphi(A_1,r_1)dA_1dr_1$$
$$- \int_{-\infty}^{\infty} \int_{K_{12}}^{\infty} \Lambda_{01}\left[\int_{-\infty}^{\infty}\int_{K_{22}}^{\infty} \Lambda_{12}A_2\varphi(A_2,r_2|A_1,r_1)dA_2dr_2\right]$$
$$\varphi(A_1,r_1)dA_1dr_1$$
$$+ \int_{-\infty}^{\infty} \int_{K_{12}}^{\infty} \Lambda_{01}\left[\int_{-\infty}^{\infty}\int_{K_{22}}^{\infty} \Lambda_{12}X_2\varphi(A_2,r_2|A_1,r_1)dA_2dr_2\right]$$
$$\varphi(A_1,r_1)dA_1dr_1$$
$$= A_0\Pi_1^+(K_{12}) - A_0\Pi_2^+(K_{12},K_{22}) + P_{02}X_2\Pi_2^-(K_{12},K_{22}) \tag{75.58}$$

Hence, the 2-year coupon bond, returning to the original notation, is:

$$
\begin{aligned}
V_{\mathrm{GJ}}(0, T_2) &= D(0, T_1) + D(0, T_2) \\
&= D(0, T_1) + \Delta_1 + \Delta_2 \\
&= P(0, T_1) X_1 \Pi_1^-(X_1) + P(0, T_2) X_2 \Pi_2^-(K_{12}, X_2) \\
&\quad + A_0 [1 - \Pi_2^+(K_{12}, X_2)]
\end{aligned}
\tag{75.59}
$$

where

$$
\Pi_1^\pm(K) = \int_{-\infty}^{\infty} \int_{K}^{\infty} \varphi^\pm(A_1, r_1) dA_1 dr_1
$$

$$
\Pi_2^\pm(K_1, K_2) = \int_{-\infty}^{\infty} \int_{K_1}^{\infty} \int_{K_2}^{\infty} \varphi^\pm(A_1, A_2, r_1) dA_2 dA_1 dr_1
\tag{75.60}
$$

It is shown in Appendix A that the last two integrals in the above equation can be written as:

$$
\int_{K}^{\infty} A_1 \varphi^-(A_1 | r_1) dA_1 = A_0 \int_{K}^{\infty} \varphi^+(A_1 | r_1) dA_1
\tag{75.61}
$$

and

$$
\int_{K_1}^{\infty} \int_{K_2}^{\infty} A_2 \varphi^-(A_1, A_2 | r_1) dA_2 dA_1 = A_0 \int_{K_1}^{\infty} \int_{K_2}^{\infty} \varphi^+(A_1, A_2 | r_1) dA_2 dA_1
\tag{75.62}
$$

where the density is adjusted by the volatility.

Following the same procedure, although tedious, we can derive the 3-year zero as:

$$
\begin{aligned}
D(0, T_3) &= P(0, T_1) X_1 [\Pi_1^-(K_{13}) - \Pi_1^-(K_{12})] \\
&\quad + P(0, T_2) X_2 [\Pi_2^-(K_{13}, K_{23}) - \Pi_2^-(K_{12}, K_{22})] \\
&\quad + P(0, T_3) X_3 \Pi_3^-(K_{13}, K_{23}, K_{33}) \\
&\quad + A(0) [\Pi_2^+(K_{12}, K_{22}) - \Pi_3^+(K_{13}, K_{23}, K_{33})]
\end{aligned}
\tag{75.63}
$$

Now, we should observe a pattern for the zero coupon bond prices, which gives (75.24).

Implementation of (75.24)

The closed form Geske-Johnson model (with constant volatility and constant interest rates) can be computed efficiently only when $n \leq 2$. When $n > 2$, then the multi-variate normal probability functions can not be implemented efficiently, particularly in high dimensions. We use the standard equity binomial model with various payoffs to pick up the survival probabilities, zero bond values, and the equity (compound option) value.[16] Note that in the binomial model, there is no need to solve for the implied strike price, K_{ij}. The (compound) option value is directly computed off the actual strikes, X_i.

In (75.24), we have both volatility and interest rate to be non-constant. We allow volatility to be a deterministic function of time (for calibration) and interest rates to be random (to capture interest rate risk). We shall sketch briefly in this appendix how (75.24) is implemented.

First, the deterministic volatility function is handled by changing time interval, suggested by Amin (1991). In the binomial model, the up and down sizes are determined by:

$$
\begin{aligned}
u &= e^{\sigma \sqrt{\Delta t}} \\
d &= e^{-\sigma \sqrt{\Delta t}}
\end{aligned}
\tag{75.64}
$$

If the volatility is changing over time, we simply adjust Δt so that $\sigma \sqrt{\Delta t}$ is constant. In this case, both u and d are constants over time and the tree recombines.

To incorporate stochastic interest rates, we first build a lattice for a "risk-neutral" bivariate Brownian motion process:

$$
\begin{aligned}
\begin{bmatrix} d \ln A \\ dr \end{bmatrix} &= \begin{bmatrix} r - \sigma^2/2 \\ \alpha(\mu - r) \end{bmatrix} dt + \begin{bmatrix} \sigma & 0 \\ 0 & \delta \end{bmatrix} \\
&\quad \times \begin{bmatrix} \sqrt{1 - \rho^2} & \rho \\ 0 & 1 \end{bmatrix} \times \begin{bmatrix} dW_1 \\ dW_2 \end{bmatrix}
\end{aligned}
\tag{75.65}
$$

where $E[dW_1 dW_2] = 0$. We then set up a binomial lattice as follows:

$$
\begin{array}{c}
\sqrt{\Delta t} \\
0 \\
-\sqrt{\Delta t}
\end{array}
$$

We label asset value and interest rate at various nodes as follows:

$$
\begin{array}{ccc}
& & < \ln A_{22}, r_{22} > \\
& < \ln A_{11}, r_{11} > & \\
< \ln A_0, r_0 > & & < \ln A_{21}, r_{21} > \\
& < \ln A_{10}, r_{10} > & \\
& & < \ln A_{20}, r_{20} >
\end{array}
$$

---

[16] We learned via private conversation that the implementation of the Geske-Johnson model in Eom et al. (2002) is computed using the binomial model.

Then we first show that the asset values recombine. Given that:

$$\ln A_{11} = \ln A_0 + (r_0 - \sigma^2/2)\Delta t + \sigma\sqrt{\Delta t}$$
$$\ln A_{10} = \ln A_0 + (r_0 - \sigma^2/2)\Delta t - \sigma\sqrt{\Delta t} \quad (75.66)$$

It is straightforward that:

$$\ln A_{21} = \ln A_{10} + (r_0 - \sigma^2/2)\Delta t + \sigma\sqrt{\Delta t}$$
$$= \ln A_{11} + (r_0 - \sigma^2/2)\Delta t - \sigma\sqrt{\Delta t} \quad (75.67)$$

We now show that the interest rate lattice recombines approximately. Note that:

$$r_{11} = r_0(1 - \alpha\Delta t) + \alpha\mu\Delta t + \delta\sqrt{\Delta t}$$
$$r_{10} = r_0(1 - \alpha\Delta t) + \alpha\mu\Delta t - \delta\sqrt{\Delta t} \quad (75.68)$$

Hence,

$$r_{21} = r_{10}(1 - \alpha\Delta t) + \alpha\mu\Delta t + \delta\sqrt{\Delta t}$$
$$= [r_0(1 - \alpha\Delta t) + \alpha\mu\Delta t - \delta\sqrt{\Delta t}](1 - \alpha\Delta t)$$
$$\quad + \alpha\mu\Delta t + \delta\sqrt{\Delta t}$$
$$= r_0(1 - 2\alpha\Delta t) + 2\alpha\mu\Delta t$$
$$= r_{11}(1 - \alpha\Delta t) + \alpha\mu\Delta t - \delta\sqrt{\Delta t} \quad (75.69)$$

This result is an approximated one because higher order terms are ignored.[17]

Closed Form Solution for $v(0, T_i)$: Rabinovitch

Following the interest rate model defined in Appendix D (i.e. the Vasicek model), the zero coupon bond price satisfies the following closed form equation (Rabinovitch, 1989):

$$P(0, t) = e^{-rF(0,t) - G(0,t)} \quad (75.70)$$

where

$$F(0, t) = \frac{1 - e^{-\alpha t}}{\alpha}$$

$$G(0, t) = (t - F(0, t))\left(\mu - \frac{\delta^2}{2\alpha}\right) + \frac{\delta^2 F(0, t)^2}{4\alpha}$$

Hence, by Ito's lemma we have,

$$\sigma_P^2(t, T_i) = \left[\frac{\partial P(t, T_i)}{\partial r}\delta\right]^2 = F(t, T_i)^2\delta^2 \quad (75.71)$$

and

$$\int_0^t \sigma_P^2(u, T_i)\, du = \int_0^t F(u, T_i)^2\delta^2\, du = \delta^2 t$$
$$+ \left((t - 2F(0, t)) + \frac{1 - e^{-2\alpha t}}{2\alpha}\right)\left(\frac{\delta}{\alpha}\right)^2$$
$$(75.72)$$

[17] If higher order terms are not ignored, then the lattice does not combine. In the case where the lattice does not recombine, we take the average of two non-recombining values at each node and proceed. We discover that this method produces extremely close results when we compare the zero coupon bond price against the Vasicek closed form model. We use the same technique with both deterministic volatility function and random interest rate are used. Note that in here, since Δt is different period by period, the interest rate dimension of the lattice does not recombine.

Appendix A: Derivation of Dividend Discount Model

A.1 Summation of Infinite Geometric Series

Summation of geometric series can be defined as:

$$S = A + AR + AR^2 + \cdots + AR^{n-1} \tag{A.1}$$

Multiplying both sides of Equation A.1 by R, we obtain

$$RS = AR + AR^2 + \cdots + AR^{n-1} + AR^n \tag{A.2}$$

Subtracting Equation A.1 by Equation A.2, we obtain

$$S - RS = A - AR^n$$

It can be shown

$$S = \frac{A(1 - R^n)}{1 - R} \tag{A.3}$$

If R is smaller than 1, and n approaches to ∞, then R^n approaches to 0 i.e.,

$$S_\infty = A + AR + AR^2 + \cdots + AR^{n-1} + \cdots + AR^\infty, \tag{A.4}$$

then,

$$S_\infty = \frac{A}{1 - R} \tag{A.5}$$

A.2 Dividend Discount Model

Dividend Discount Model can be defined as:

$$P_0 = \frac{D_1}{1 + k} + \frac{D_2}{(1 + k)^2} + \frac{D_3}{(1 + k)^3} + \cdots \tag{A.6}$$

Where P_0 = present value of stock price per share D_t = dividend per share in period t (t = 1, 2,...,n)

If dividends grow at a constant rate, say g, then, $D_2 = D_1(1 + g)$, $D_3 = D_2(1 + g) = D_1(1 + g)^2$, and so on.
Then, Equation A.6 can be rewritten as:

$$P_0 = \frac{D_1}{1 + k} + \frac{D_1(1 + g)}{(1 + k)^2} + \frac{D_1(1 + g)^2}{(1 + k)^3} + \cdots \quad \text{or,}$$

$$P_0 = \frac{D_1}{1 + k} + \frac{D_1}{(1 + k)} \times \frac{(1 + g)}{(1 + k)} + \frac{D_1}{(1 + k)}$$

$$\times \frac{(1 + g)^2}{(1 + k)^2} + \cdots \tag{A.7}$$

Comparing Equation A.7 with Equation A.4, i.e., $P_0 = S_\infty$, $\frac{D_1}{1+k} = A$, and $\frac{1+g}{1+k} = R$ as in the Equation A.4.

Therefore, if $\frac{1+g}{1+k} < 1$ or if $k > g$, we can use Equation A.5 to find out P_0

i.e.,

$$\begin{aligned} P_0 &= \frac{D_1/(1 + k)}{1 - [(1 + g)/(1 + k)]} \\ &= \frac{D_1/(1 + k)}{[1 + k - (1 + g)]/(1 + k)} \\ &= \frac{D_1/(1 + k)}{(k - g)/(1 + k)} \\ &= \frac{D_1}{k - g} = \frac{D_0(1 + g)}{k - g} \end{aligned}$$

Appendix B: Derivation of DOL, DFL and DCL

B.1 DOL

Let P = price per unit
$\quad$ V = variable cost per unit
$\quad$ F = total fixed cost
$\quad$ Q = quantity of goods sold

The definition of DOL can be defined as:
$\quad$ DOL (Degree of operating leverage)

$$= \frac{Percentage\ Change\ in\ Profits}{Percentage\ Change\ in\ Sales}$$

$$= \frac{\Delta\,EBIT\,/\,EBIT}{\Delta Sales/Sales}$$

$$= \frac{\left\{\left[Q(P-V)-F\right]-\left[Q'(P-V)-F\right]\right\}\big/\left[Q(P-V)-F\right]}{(P\times Q - P\times Q')/(P\times Q)}$$

$$= \frac{\left[Q(P-V)-Q'(P-V)\right]\big/\left[Q(P-V)-F\right]}{P(Q-Q')/P\times Q}$$

$$= \frac{(Q-Q')(P-V)\big/\left[Q(P-V)-F\right]}{P(Q-Q')/P\times Q}$$

$$= \frac{\cancel{(Q-Q')}\,(P-V)}{Q\,(P-V)-F}\times\frac{\cancel{P}\times Q}{\cancel{P}\,\cancel{(Q-Q')}}$$

$$= \boxed{\frac{Q(P-V)}{Q(P-V)-F}}$$

$$= \frac{Q(P-V)-F+F}{Q(P-V)-F}=\frac{Q(P-V)-F}{Q(P-V)-F}+\frac{F}{Q(P-V)-F}$$

$$= 1+\frac{F}{Q(P-V)-F}$$

$$\boxed{= 1+\frac{Fixed\ Costs}{Profits}}$$

B.2 DFL

Let i = interest rate on $\left.\begin{array}{l}\text{outstanding debt}\\ D = \text{outstanding debt}\end{array}\right\}$ iD = interest payment on dept

N = the total number of shares outstanding
τ = corporate tax rate
EAIT = $[Q(P-V)-F-i\mathrm{D}](1-\tau)$

The definition of DFL can be defined as:

$\quad$ DFL (Degree of financial leverage)

$$= \frac{\Delta\,EPS/EPS}{\Delta\,EBIT\,/\,EBIT}=\frac{(\Delta\,EAIT\,/\,N)/(EAIT\,/\,N)}{\Delta\,EBIT/EBIT}$$

$$= \frac{\Delta\,EAIT/EAIT}{\Delta\,EBIT\,/\,EBIT}$$

$$= \frac{\dfrac{\left[Q(P-V)-F-i\mathrm{D}\right](1-\tau)-\left[Q'(P-V)-F-i\mathrm{D}\right]}{(1-\tau)\left[Q(P-V)-F-i\mathrm{D}\right](1-\tau)}}{\dfrac{\left[Q(P-V)-F\right]-\left[Q'(P-V)-F\right]}{\left[Q(P-V)-F\right]}}$$

$$= \frac{\dfrac{\left[Q(P-V)\right](1-\tau)-\left[Q'(P-V)\right](1-\tau)}{\left[Q(P-V)-F-i\mathrm{D}\right]-(1-\tau)}}{\dfrac{\left[Q(P-V)-Q'(P-V)\right]}{\left[Q(P-V)-F\right]}}$$

$$= \frac{\left[\cancel{(Q-Q')(P-V)}\right]\cancel{(1-\tau)}}{\left[Q\,(P-V)-F-i\mathrm{D}\right]\cancel{(1-\tau)}}\times\frac{Q\,(P-V)-F}{\cancel{(Q-Q')(P-V)}}$$

$$= \boxed{\frac{Q(P-V)-F}{Q(P-V)-F-i\mathrm{D}}}\left(=\frac{EBIT}{EBIT\text{ - }i\mathrm{D}}\right)$$

B.3   DCL (Degree of Combined Leverage)

$$= \text{DOL} \times \text{DFL}$$

$$= \frac{Q\,(\text{P}-\text{V})}{\cancel{Q\,(\text{P}-\text{V})-\text{F}}} \times \frac{\cancel{Q\,(\text{P}-\text{V})-\text{F}}}{Q\,(\text{P}-\text{V})-\text{F}-i\text{D}} = \boxed{\frac{Q\left(P-V\right)}{Q\left(P-V\right)-F-i\text{D}}}$$

Appendix C: Derivation of Crossover Rate

Suppose there are two projects under consideration. Cash flows of project A, B and B − A are as follows:

Period	0	1	2	3
Project A	−10,500	10,000	1,000	1,000
Project B	−10,500	1,000	1,000	12,000
Cash flows of B − A	0	−9,000	0	11,000

Table A.1 NPV of Project A and B under different discount rates

Discount rate (%)	NPV (Project A)	NPV (Project B)
0	1500.00	3500.00
5	794.68	1725.46
10	168.67	251.31
15	−390.69	−984.10
20	−893.52	−2027.78

Based upon the information the table above we can calculate the NPV of Project A and Project B under different discount rates. The results are presented in Table A.1.

NPV(B) is higher with low discount rates and NPV(A) is higher with high discount rates. This is because the cash flows of project A occur early and those of project B occur later. If we assume a high discount rate, we would favor project A; if a low discount rate is expected, project B will be chosen. In order to make the right choice, we can calculate the crossover rate. If the discount rate is higher than the crossover rate, we should choose project A; if otherwise, we should go for project **B**. **The crossover rate, R_c, is the rate such that NPV(A) equals to NPV(B)**.

Suppose the crossover rate is R_c, then

$$\text{NPV}(A) = -10,500 + 10,000/(1+R_c) + 1,000/ (1+R_c)^2 + 1,000/(1+R_c)^3 \quad (A.8)$$

$$\text{NPV}(B) = -10,500 + 1,000/(1+R_c) + 1,000/ (1+R_c)^2 + 12,000/(1+R_c)^3$$
$$\text{NPV}(A) = \text{NPV}(B) \quad (A.9)$$

Therefore,

$$\boxed{\begin{aligned} &-10,500 + \frac{10,000}{1+R_c} + \frac{1,000}{(1+R_c)^2} + \frac{1,000}{(1+R_c)^3} \\ &= -10,500 + \frac{1,000}{1+R_c} + \frac{1,000}{(1+R_c)^2} + \frac{12,000}{(1+R_c)^3} \end{aligned}}$$

Rearranging the above equation (moving all terms on the LHS to the RHS), we obtain Equation A.10

$$0 = [-10,500 - (-10,500)] + \left[\frac{1,000}{1+R_c} - \frac{10,000}{1+R_c}\right]$$
$$+ \left[\frac{1,000}{(1+R_c)^2} - \frac{1,000}{(1+R_c)^2}\right] + \left[\frac{12,000}{(1+R_c)^3} - \frac{1,000}{(1+R_c)^3}\right] \quad (A.10)$$

Solving Equation A.10 by trial and error method for R_c, R_c equals 10.55%.

Using the procedure of calculating internal rate of return (IRR) as discussed in Equations A.8, A.9, and A.10, we calculate the IRR for both Project A and Project B. The IRR for Project A and B are 11.45% and 10.95% respectively. From this information, we have concluded that Project A will perform better than Project B without consideration for change of discount rate. Therefore, the IRR decision rule cannot be used for capital budgeting decisions when there exists an increasing or decreasing net cash inflow. This is so called "The Timing Problem" for using the IRR method for capital budgeting decisions.

This page intentionally left blank

Appendix D: Capital Budgeting Decisions with Different Lives

D.1 Mutually Exclusive Investment Projects with Different Lives

The traditional NPV technique may not be the appropriate criterion to select a project from mutually exclusive investment projects, if these projects have different lives. The underlying reason is that, compared with a long-life project, a short-life project can be replicated more quickly in the long run. In order to compare projects with different lives, we compute the NPV of an infinite replication of the investment project. For example, let Projects A and B be two mutually exclusive investment projects with the following cash flows.

Year	Project A	Project B
0	100	100
1	70	50
2	70	50
3		50

By assuming a discount rate of 12%, the traditional NPV of Project A is 18.30 and the NPV of Project B is 20.09. This shows that Project B is a better choice than Project A. However, the NPV with infinite replications for Project A and B should be adjusted into a comparable basis.

In order to compare Projects A and B, we compute the NPV of an infinite stream of constant scale replications. Let NPV (N, ∞) be the NPV of an N-year project with NPV (N), replicated forever. This is exactly the same as an annuity paid at the beginning of the first period and at the end of every N years from that time on. The NPV of the annuity is:

$$NPV(N, \infty) = NPV(N) + \frac{NPV(N)}{(1+K)^N} + \frac{NPV(N)}{(1+K)^{2N}} + \cdots$$

In order to obtain a closed-form formula, let $(1/[(1 + K)^N]) = H$. Then we have:

$$NPV(N, \ t) = NPV(N)\left(1 + H + H^2 + \cdots + H^t\right) \quad (A.11)$$

Multiplying both sides by H, this becomes

$$H[NPV(N, \ t)] = NPV(N)\left(H + H^2 + \cdots + H^t + H^{t+1}\right) \quad (A.12)$$

Subtracting Equation A.12 from Equation A.11 gives:

$$NPV(N, \ t) - (H)NPV(N, \ t) = NPV(N)\left(1 - H^{t+1}\right)$$
$$NPV(N, \ t) = \frac{NPV(N)\left(1 - H^{t+1}\right)}{1 - H}$$

Taking the limit as the number of replications, t, approaches infinity gives:

$$\lim_{x \to \infty} NPV(N, \ t) = NPV(N, \ \infty)$$

$$= NPV\left[\frac{1}{1 - \left[1/(1+K)^N\right]}\right]$$

$$= NPV(N)\left[\frac{(1+K)^N}{(1+K)^N - 1}\right] \quad (A.13)$$

Equation A.13 is the NPV of an N-year project replicated at constant scale an infinite number of times. We can use it to compare projects with different lives because when their cash-flow streams are replicated forever, it is as if they had the same (infinite) life.

Based upon Equation A.13, we can calculate the NPV of Projects A and B as follows:

For Project A

$NPV(2, \ \infty)$

$= NPV(2)\left[\frac{(1 + 0.12)^2}{(1 + 0.12)^2 - 1}\right]$

$= (18.30)\left[\frac{1.2544}{0.2544}\right]$

$= 90.23$

For Project B

$NPV(3, \ \infty)$

$= NPV(3)\left[\frac{(1 + 0.12)^3}{(1 + 0.12)^3 - 1}\right]$

$= 20.09\left[\frac{1.4049}{0.4049}\right]$

$= 69.71$

Consequently, we would choose to accept Project A over Project B, because, when the cash flows are adjusted for different lives, A provides the greater cash flow.

Alternatively, Equation A.13 can be rewritten as an equivalent annual NPV version as:

$$K \times NPV(N, \infty) = \frac{NPV(N)}{Annuity\ factor} \qquad (A.14)$$

where the annuity factor is

$$\frac{1 - 1\big/(1+K)^N}{K}$$

The decision rule from Equation A.14 is equivalent to the decision rule of Equation A.13.

The different project lives can affect the beta coefficient estimate, as shown by Meyers and Turnbull (1977). For empirical guidance for evaluating capital-investment alternatives with unequal lives, the readers are advised to refer Emery (1982).

D.2 Equivalent Annual Cost

Equation A.14 can be written as:

$$NPV(N) = K \times NPV(N, \infty) \times Annuity\ Factor \qquad (A.15)$$

Corporate Finance by Ross, Westerfield, and Jaffe (2005, 7th edn, p. 193) has discussed about Equivalent Annual Cost. The Equivalent Annual Cost (C) can be calculated as follows:

$$NPV(N) = C \times Annuity\ Factor \qquad (A.16)$$

From Equations A.15 and A.16, we obtain

$$C = K \times NPV(N, \infty) \qquad (A.17)$$

Assume company A buys a machine that costs \$1,000 and the maintenance expense of \$250 is to be paid at the end of each of the 4 years. To evaluate this investment, we can calculate the present value of the machine. Assuming the discount rate as 10%, we have

$$NPV(A) = 1000 + \frac{250}{1.1} + \frac{250}{(1.1)^2} + \frac{250}{(1.1)^3} + \frac{250}{(1.1)^4}$$
$$= 1792.47$$

$$(A.18)$$

Equation A.18 shows that payments of (1,000, 250, 250, 250, 250) are equivalent to a payment of 1792.47 at time 0. Using Equation A.16, we can equate the payment at time 0 of 1792.47 with a 4 year annuity.

$$1792.47 = C \times A_{0.1}^4 = C \times 3.1699$$
$$C = 565.47$$

In this example, following Equation A.13, we can find

$$NPV(N, \infty) = 1749.47 \times (1 + 0.1)^4 / [(1 + 0.1)^4 - 1]$$
$$= 5654.71$$

Then following the Equation A.17, we obtain

$$C = K \times NPV(N, \infty) = 0.1 \times 5654.71 = 565.47$$

Therefore, the equivalent annual cost C is identical to the equivalent annual NPV as defined in Equation A.14.

Appendix E: Derivation of Minimum-Variance Portfolio

If there is a two security portfolio, its variance can be defined as:

$$\sigma_p^2 = w_D^2 \sigma_D^2 + w_E^2 \sigma_E^2 + 2 w_D w_E \text{Cov}(r_D, r_E) \qquad \text{(A.19)}$$

where r_D and r_E are the rate of return for security D and security E respectively; w_D and w_E are weight associated with security D and E respectively; σ_D^2 and σ_E^2 are variance of security D and E respectively; and $\text{Cov}(r_D, r_E)$ is the covariance between r_D and r_E.

The problem is choosing optimal w_D to minimize the portfolio variance, σ_p^2

$$\underset{w_D}{Min} \ \sigma_P^2 \qquad \text{(A.20)}$$

We can solve the minimization problem by differentiating the σ_p^2 with respect to w_D and setting the derivative equal to 0 i.e., we want to solve

$$\frac{\partial \sigma_p^2}{\partial w_D} = 0 \qquad \text{(A.21)}$$

Since, $w_D + w_E = 1$ or, $w_E = 1 - w_D$ therefore, the variance, σ_P^2, can be rewritten as

$$
\begin{aligned}
\sigma_p^2 &= w_D^2 \sigma_D^2 + w_E^2 \sigma_E^2 + 2 w_D w_E \ \text{Cov}(r_D, r_E) \\
&= w_D^2 \sigma_D^2 + (1 - w_D)^2 \sigma_E^2 + 2 w_D (1 - w_D) \ \text{Cov}(r_D, r_E) \\
&= w_D^2 \sigma_D^2 + \sigma_E^2 - 2 w_D \sigma_E^2 + w_D^2 \sigma_E^2 + 2 w_D \ \text{Cov}(r_D, r_E) \\
&\quad - 2 w_D^2 \text{Cov}(r_D, r_E)
\end{aligned}
$$

Now, the first order conditions of Equation A.21 can be written as

$$2 w_D \sigma_D^2 - 2 \sigma_E^2 + 2 w_D \sigma_E^2 + 2 \ \text{Cov}(r_D, r_E) - 4 w_D$$
$$\text{Cov}(r_D, r_E) = 0$$

Rearranging the above equation,

$$w_D \sigma_D^2 + w_D \sigma_E^2 - 2 w_D \ \text{Cov}(r_D, r_E) = \sigma_E^2 - \text{Cov}(r_D, r_E)$$
$$\left[\sigma_D^2 + \sigma_E^2 - 2 \text{Cov}(r_D, r_E)\right] w_D = \sigma_E^2 - \text{Cov}(r_D, r_E)$$

Finally, we have

$$\boxed{w_D = \frac{\sigma_E^2 - \text{Cov}(r_D, r_E)}{\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D, r_E)}}$$

This page intentionally left blank

Appendix F: Derivation of an Optimal Weight Portfolio Using the Sharpe Performance Measure

Solution for the weights of the optimal risky portfolio can be found by solving the following maximization problem:

$$\underset{w_D}{Max}\, S_p = \frac{E(r_p) - r_f}{\sigma_p}$$

where $E(r_p)$ = expected rates of return for portfolio P
r_f = risk free rates of return
S_p = sharpe performance measure, and
σ_p as defined in Equation A.19 of Appendix 5
We can solve the maximization problem by differentiating the S_p with respect to w_D, and setting the derivative equal to 0 i.e., we want to solve

$$\frac{\partial S_p}{\partial w_D} = 0 \qquad (A.22)$$

In the case of two securities, we know that

$$E(r_p) = w_D\, E(r_D) + w_E\, E(r_E) \qquad (A.23)$$

$$\sigma_p = \left[w_D^2 \sigma_D^2 + w_E^2 \sigma_E^2 + 2w_D\, w_E\, \mathrm{Cov}(r_D,\, r_E)\right]^{1/2} \quad (A.24)$$

$$w_D + w_E = 1 \qquad (A.25)$$

From above Equations A.23, A.24, and A.25, we can rewrite $E(r_p) - r_f$ and σ_p as:

$$
\begin{aligned}
E(r_p) - r_f &= w_D\, E(r_D) + w_E\, E(r_E) - r_f\\
&= w_D\, E(r_D) + (1 - w_D)\, E(r_E) - r_f\\
&\equiv f(w_D)
\end{aligned}
\qquad (A.26)
$$

$$
\begin{aligned}
\sigma_p &= \left[w_D^2\, \sigma_D^2 + w_E^2\, \sigma_E^2 + 2w_D w_E\, \mathrm{Cov}(r_D,\, r_E)\right]^{1/2}\\
&= \big[w_D^2\, \sigma_D^2 + (1 - w_D)^2\, \sigma_E^2 + 2w_D(1 - w_D)\\
&\quad \mathrm{Cov}(r_D,\, r_E)\big]^{1/2}\\
&\equiv g(w_D)
\end{aligned}
\qquad (A.27)
$$

Equation A.22 becomes

$$
\begin{aligned}
\frac{\partial S_p}{\partial w_D} &= \frac{\partial [f(w_D)/g(w_D)]}{\partial w_D}\\
&= \frac{f'(w_D)g(w_D) - f(w_D)g'(w_D)}{[g(w_D)]^2} = 0
\end{aligned}
\qquad (A.28)
$$

where $f'(w_D) = \dfrac{\partial f(w_D)}{\partial w_D} = E(r_D) - E(r_E)$ $\qquad (A.29)$

$$
\begin{aligned}
g'(w_D) &= \frac{\partial g(w_D)}{\partial w_D}\\
&= \frac{1}{2} \times \big[w_D^2 \sigma_D^2 + (1 - w_D)^2 \sigma_E^2 + 2w_D(1 - w_D)\\
&\qquad \mathrm{Cov}(r_D, r_E)\big]^{1/2 - 1}\\
&\qquad \times \big[2w_D\sigma_D^2 + 2w_D\sigma_E^2 - 2\sigma_E^2 + 2\mathrm{Cov}(r_D, r_E)\\
&\qquad - 4w_D\, \mathrm{Cov}(r_D, r_E)\big]\\
&= \big[w_D\sigma_D^2 + w_D\sigma_E^2 - \sigma_E^2 + \mathrm{Cov}(r_D, r_E)\\
&\qquad - 2w_D\, \mathrm{Cov}(r_D, r_E)\big]\\
&\qquad \times \big[w_D^2 \sigma_D^2 + (1 - w_D)^2 \sigma_E^2 + 2w_D(1 - w_D)\\
&\qquad \mathrm{Cov}(r_D, r_E)\big]^{-1/2}
\end{aligned}
$$
$$(A.30)$$

From Equation A.28,

$$
\begin{aligned}
f'(w_D)g(w_D) - f(w_D)g'(w_D) &= 0,\ \text{or}\\
f'(w_D)g(w_D) &= f(w_D)g'(w_D)
\end{aligned}
\qquad (A.31)
$$

Now, plugging $f(w_D)$, $g(w_D)$, $f'(w_D)$, and $g'(w_D)$ [Equations A.26, A.27, A.29, and A.30] into Equation A.31, we have

$$
\begin{aligned}
&[E(r_D) - E(r_E)]\\
&\quad \times \big[w_D^2\sigma_D^2 + (1 - w_D)^2\sigma_E^2 + 2W_D(1 - w_D)\mathrm{Cov}(r_D, r_E)\big]^{1/2}\\
&= [w_D E(r_D) + (1 - w_D)E(r_E) - r_f]\\
&\quad \times \big[w_D\sigma_D^2 + w_D\sigma_E^2 - \sigma_E^2 + \mathrm{Cov}(r_D, r_E)\\
&\qquad - 2w_D\mathrm{Cov}(r_D, r_E)\big]\\
&\quad \times \big[w_D^2\sigma_D^2 + (1 - w_D)^2\sigma_E^2 + 2w_D(1 - w_D)\\
&\qquad \mathrm{Cov}(r_D, r_E)\big]^{-1/2}
\end{aligned}
$$
$$(A.31)$$

Multiplying by $\left[w_D^2\sigma_D^2 + (1-w_D)^2\sigma_E^2 + 2w_D(1-w_D)\right.$ $\left.\text{Cov}(r_D,\ r_E)\right]^{1/2}$ on both sides of Equation A.32, we have

$$
\begin{aligned}
&[E(r_D) - E(r_E)] \\
&\quad \times \left[w_D^2\sigma_D^2 + (1-w_D)^2\sigma_E^2 + 2w_D(1-w_D)\text{Cov}(r_D,r_E)\right] \\
&= [w_D E(r_D) + (1-w_D)E(r_E) - r_f] \\
&\quad \times \left[w_D\sigma_D^2 + w_D\sigma_E^2 - \sigma_E^2 + \text{Cov}(r_D,r_E) - 2w_D\text{Cov}(r_D,r_E)\right]
\end{aligned}
$$
$$(A.33)$$

Rearrange all terms on both hand sides of Equation A.33, i.e.,
Left hand side of Equation A.33

$$
\begin{aligned}
&[E(r_D) - E(r_E)] \\
&\quad \times \left[w_D^2\sigma_D^2 + (1-w_D)^2\sigma_E^2 + 2w_D(1-w_D)\text{Cov}(r_D,r_E)\right] \\
&= [E(r_D) - E(r_E)] \\
&\quad \times \left[w_D^2\sigma_D^2 + \sigma_E^2 - 2w_D\sigma_E^2 + w_D^2\sigma_E^2 + 2w_D\text{Cov}(r_D,r_E)\right. \\
&\qquad \left. - 2w_D^2\text{Cov}(r_D,r_E)\right] \\
&= [E(r_D) - E(r_E)] \times \{w_D^2[\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D,r_E)] \\
&\qquad + 2w_D[\text{Cov}(r_D,r_E) - \sigma_E^2] + \sigma_E^2\} \\
&= [E(r_D) - E(r_E)] \times \{w_D^2[\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D,r_E)]\} \\
&\quad + [E(r_D) - E(r_E)] \times \{2w_D[\text{Cov}(r_D,r_E) - \sigma_E^2]\} + [E(r_D) \\
&\quad - E(r_E)] \times \sigma_E^2 = [E(r_D) - E(r_E)] \times [\sigma_D^2 + \sigma_E^2 \\
&\quad - 2\text{Cov}(r_D,r_E)]w_D^2 + 2[E(r_D) - E(r_E)] \\
&\quad \times [\text{Cov}(r_D,r_E) - \sigma_E^2]w_D + [E(r_D) - E(r_E)] \times \sigma_E^2
\end{aligned}
$$

Right hand side of Equation A.33

$$
\begin{aligned}
&[w_D E(r_D) + (1-w_D)E(r_E) - r_f] \times [w_D\sigma_D^2 + w_D\sigma_E^2 \\
&\quad - \sigma_E^2 + \text{Cov}(r_D,r_E) - 2w_D\text{Cov}(r_D,r_E)] \\
&= [w_D E(r_D) + E(r_E) - w_D E(r_E) - r_f] \times [w_D\sigma_D^2 \\
&\quad + w_D\sigma_E^2 - 2w_D\text{Cov}(r_D,r_E) - \sigma_E^2 + \text{Cov}(r_D,r_E)] \\
&= \{w_D[E(r_D) - E(r_E)] + [E(r_E) - r_f]\} \times \{w_D[\sigma_D^2 \\
&\quad + \sigma_E^2 - 2\text{Cov}(r_D,r_E)] + \text{Cov}(r_D,r_E) - \sigma_E^2\} \\
&= w_D[E(r_D) - E(r_E)] \times w_D[\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D,r_E)] \\
&\quad + w_D[E(r_D) - E(r_E)] \times [\text{Cov}(r_D,r_E) - \sigma_E^2] \\
&\quad + [E(r_E) - r_f] \times w_D[\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D,r_E)] \\
&\quad + [E(r_E) - r_f] \times [\text{Cov}(r_D,r_E) - \sigma_E^2] \\
&= [E(r_D) - E(r_E)] \times [\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D,r_E)]w_D^2 \\
&\quad + [E(r_D) - E(r_E)] \times [\text{Cov}(r_D,r_E) - \sigma_E^2]w_D \\
&\quad + [E(r_E) - r_f] \times [\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D,r_E)]w_D \\
&\quad + [E(r_E) - r_f] \times [\text{Cov}(r_D,r_E) - \sigma_E^2]
\end{aligned}
$$

Subtracting
$[E(r_D) - E(r_E)][\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D,r_E)]w_D^2$ and $[E(r_D) - E(r_E)][\text{Cov}(r_D,r_E) - \sigma_E^2]w_D$ from both hand sides of Equation A.33, we have

$$
\begin{aligned}
&[E(r_D) - E(r_E)] \times [\text{Cov}(r_D,r_E) - \sigma_E^2]w_D \\
&\quad + [E(r_D) - E(r_E)] \times \sigma_E^2 \\
&= [E(r_E) - r_f] \times [\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D,r_E)]w_D \\
&\quad + [E(r_E) - r_f] \times [\text{Cov}(r_D,r_E) - \sigma_E^2]
\end{aligned}
$$
$$(A.34)$$

Moving all the terms with w_D on one side and leaving the rest terms on the other side from Equation A.34, we have

$$
\begin{aligned}
&[E(r_D) - E(r_E)] \times \sigma_E^2 - [E(r_E) - r_f] \\
&\quad \times [\text{Cov}(r_D,r_E) - \sigma_E^2] \\
&= [E(r_E) - r_f] \times [\sigma_D^2 + \sigma_E^2 - 2\text{Cov}(r_D,r_E)]w_D \\
&\quad - [E(r_D) - E(r_E)] \times [\text{Cov}(r_D,r_E) - \sigma_E^2]w_D
\end{aligned}
$$
$$(A.35)$$

Rearrange Equation A.35 in order to solve for w_D, i.e.,

$$
\begin{aligned}
&[E(r_D) - E(r_E) + E(r_E) - r_f] \times \sigma_E^2 \\
&\quad - [E(r_E) - r_f]\text{Cov}(r_D,r_E) \\
&= \{[E(r_E) - r_f]\sigma_D^2 + [E(r_E) - r_f]\sigma_E^2 \\
&\quad - [E(r_E) - r_f][2\text{Cov}(r_D,r_E)] - [E(r_D) \\
&\quad - E(r_E)]\text{Cov}(r_D,r_E) + [E(r_D) - E(r_E)]\sigma_E^2\}w_D \\
&= \{[E(r_D) - r_f]\sigma_E^2 + [E(r_E) - r_f]\sigma_D^2 - [E(r_D) \\
&\quad - r_f + E(r_E) - r_f]\text{Cov}(r_D,r_E)]\}w_D
\end{aligned}
$$

Finally, we have the optimum weight of security D as

$$
w_D = \frac{[E(r_D) - r_f]\sigma_E^2 - [E(r_E) - r_f]\text{Cov}(r_D,r_E)}{[E(r_D) - r_f]\sigma_E^2 + [E(r_E) - r_f]\sigma_D^2} \\
- [E(r_D) - r_f + E(r_E) - r_f]\text{Cov}(r_D,r_E)
$$

Appendix G: Applications of the Binomial Distribution to Evaluate Call Options

In this appendix, we show how the binomial distribution is combined with some basic finance concepts to generate a model for determining the price of stock options.

G.1 What is an Option?

In the most basic sense, an **option** is a contract conveying the right to buy or sell a designated security at a stipulated price. The contract normally expires at a predetermined date. The most important aspect of an option contract is that the purchaser is under no obligation to buy; it is, indeed, an "option." This attribute of an option contract distinguishes it from other financial contracts. For instance, whereas the holder of an option may let his or her claim expire unused if he or she so desires, other financial contracts (such as futures and forward contracts) obligate their parties to fulfill certain conditions.

A *call option* gives its owner the right to buy the underlying security, a *put option* the right to sell. The price at which the stock can be bought (for a call option) or sold (for a put option) is known as the exercise price.

G.2 The Simple Binomial Option Pricing Model

Before discussing the binomial option model, we must recognize its two major underlying assumptions. First, the binomial approach assumes that trading takes place in discrete time, that is, on a period-by-period basis. Second, it is assumed that the stock price (the price of the underlying asset) can take on only two possible values each period; it can go up or go down.

Say we have a stock whose current price per share S can advance or decline during the next period by a factor of either u (up) or d (down). This price either will increase by the proportion $u - 1 \geq 0$ or will decrease by the proportion $1 - d, 0 < d < 1$. Therefore, the value S in the next period will be either uS or dS. Next, suppose that a call option exists on this stock with a current price per share of C and an exercise price per share of X and that the option has one period left to maturity. This option's value at expiration is determined by the price of its underlying stock and the exercise price X. The value is either

$$C_u = Max(0, \ uS - X) \qquad (A.36)$$

or

$$C_d = Max(0, \ dS - X) \qquad (A.37)$$

Why is the call worth Max $(0, \ uS - X)$ if the stock price us uS? The option holder is not obliged to purchase the stock at the exercise price of X, so she or he will exercise the option only when it is beneficial to do so. This means the option can never have a negative value. When is it beneficial for the option holder to exercise the option? When the price per share of the stock is greater than the price per share at which he or she can purchase the stock by using the option, which is the exercise price, X. Thus if the stock price uS exceeds the exercise price X, the investor can exercise the option and buy the stock. Then he or she can immediately sell it for uS, making a profit of $uS - X$ (ignoring commission). Likewise, if the stock price declines to dS, the call is worth Max $(0, \ dS - X)$.

Also for the moment, we will assume that the risk-free interest rate for both borrowing and lending is equal to r percent over the one time period and that the exercise price of the option is equal to X.

To intuitively grasp the underlying concept of option pricing, we must set up a *risk-free portfolio* – a combination of assets that produces the same return in every state of the world over our chosen investment horizon. The investment horizon is assumed to be one period (the duration of this period can be any length of time, such as an hour, a day, a week, etc.). To do this, we buy h share of the stock and sell the call option at its current price of C. Moreover, we choose the value of h such that our portfolio will yield the same payoff whether the stock goes up or down.

$$h(uS) - C_u = h(dS) - C_d \qquad (A.38)$$

By solving for h, we can obtain the number of shares of stock we should buy for each call option we sell.

$$h = \frac{C_u - C_d}{(u - d)S} \qquad (A.39)$$

Here h is called the *hedge ratio*. Because our portfolio yields the same return under either of the two possible states for the stock, it is without risk and therefore should yield the risk-free rate of return, r percent, which is equal to the risk-free borrowing and lending rate, the condition must be true; otherwise, it would be possible to earn a risk-free profit without using any money. Therefore, the ending portfolio value must be equal to $(1 + r)$ times the beginning portfolio value, $hS - C$.

$$(1 + r)(hS - C) = h(uS) - C_u = h(dS) - C_d \qquad (A.40)$$

Note that S and C represent the beginning values of the stock price and the option price, respectively.

Setting $R = 1 + r$, rearranging to solve for C, and using the value of h from Equation A.39, we get

$$C = \left[\left(\frac{R - d}{u - d} \right) C_u + \left(\frac{u - R}{u - d} \right) C_d \right] \Big/ R \qquad (A.41)$$

where $d < r < u$. To simplify this equation, we set

$$p = \frac{R - d}{u - d} \text{ so } 1 - p = \left\{ \frac{u - R}{u - d} \right\} \qquad (A.42)$$

Thus we get the option's value with one period to expiration

$$C = \frac{pC_u + (1 - p)C_d}{R} \qquad (A.43)$$

This is the binomial call option valuation formula in its most basic form. In other words, this is the binomial valuation formula with one period to expiration of the option.

To illustrate the model's qualities, let's plug in the following values, while assuming the option has one period to expiration. Let

$$X = \$100$$
$$S = \$100$$
$$U = (1.10), \text{ so } uS = \$110$$
$$D = (0.90), \text{ so } dS = \$90$$
$$R = 1 + r = 1 + 0.07 = 1.07$$

First we need to determine the two possible option values at maturity, as indicated in Table A.2.

Next we calculate the value of p as indicated in Equation A.42.

Table A.2 Possible option value at maturity

Today Stock (S)	Option (C)	Next Period (Maturity)
	$uS=\$110$	$C_u = Max(0, uS - X)$
		$= Max(0, 110 - 100)$
$\$100$ C		$= Max(0, 10)$
		$= \$10$
	$dS=\$90$	$C_d = Max(0, dS - X)$
		$= Max(0, 90 - 100)$
		$= Max(0, -10)$
		$= \$0$

$$p = \frac{1.07 - 0.90}{1.10 - 0.90} = 0.85 \text{ so } 1 - p = \frac{1.10 - 1.07}{1.10 - 0.90}$$
$$= 0.15$$

Solving the binomial valuation equation as indicated in Equation A.43, we get

$$C = \frac{0.85(10) + 0.15(0)}{1.07}$$
$$= \$7.94$$

The correct value for this particular call option today, under the specified conditions, is \$7.94. If the call option does not sell for \$7.94, it will be possible to earn arbitrage profits. That is, it will be possible for the investor to earn a risk-free profit while using none of his or her own money. Clearly, this type of opportunity cannot continue to exist indefinitely.

G.3   The Generalized Binomial Option Pricing Model

Suppose we are interested in the case where there is more than one period until the option expires. We can extend the one-period binomial model to consideration of two or more periods.

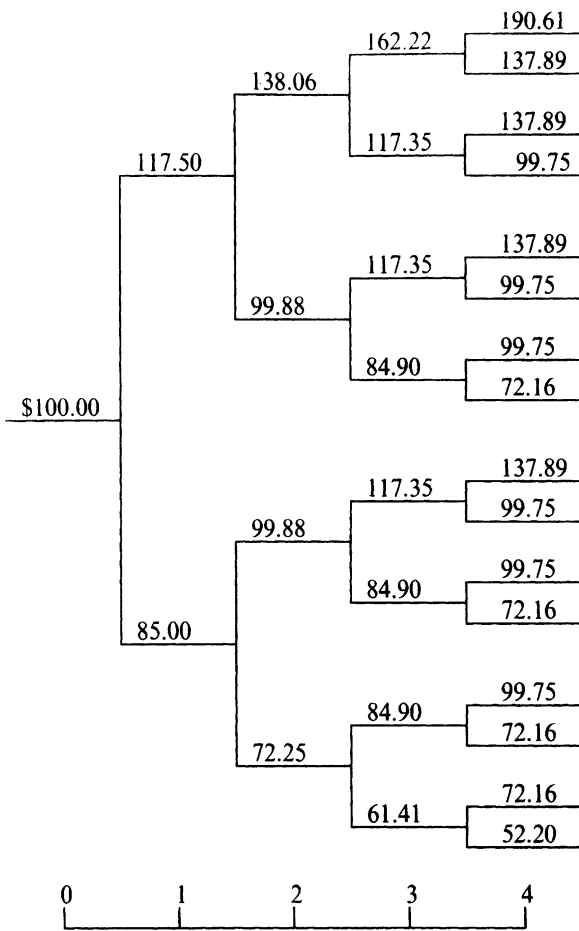
Because we are assuming that the stock follows a binomial process, from one period to the next it can only go up by a factor of u or go down by a factor of d. After one period the stock's price is either uS or dS. Between the first and second periods, the stock's price can once again go up by u or down by d, so the possible prices for the stock two periods from now are uuS, udS, and ddS. This process is demonstrated in


Fig. A.1 Price path of underlying stock (Source: Rendelman and Bartter, 1979, 1906)

tree diagram (Figure A.1) given in Example A.1 later in this appendix.

Note that the option's price at expiration, two periods from now, is a function of the same relationship that determined its expiration price in the one-period model, more specifically, the call option's maturity value is always

$$C_T = [0, S_T - X] \tag{A.44}$$

where T designated the maturity date of the option.

To derive the option's price with two periods to go ($T = 2$), it is helpful as an intermediate step to derive the value of C_u and C_d with one period to expiration when the stock price is either uS or dS, respectively.

$$C_u = \frac{pC_{uu} + (1-p)C_{ud}}{R} \tag{A.45}$$

$$C_d = \frac{pC_{du} + (1-p)C_{dd}}{R} \tag{A.46}$$

Equation A.45 tells us that if the value of the option after one period is C_u, the option will be worth either C_{uu} (if the stock price goes up) or C_{ud} (if stock price goes down) after one more period (at its expiration date). Similarly, Equation A.46 shows that the value of the option is C_d after one period, the option will be worth either C_{du} or C_{dd} at the end of the second period. Replacing C_u and C_d in Equation A.43 with their expressions in Equations A.45 and A.46, respectively, we can simplify the resulting equation to yield the two-period equivalent of the one-period binomial pricing formula, which is

$$C = \frac{p^2 C_{uu} + 2p(1-p)C_{ud} + (1-p)^2 C_{dd}}{R^2} \tag{A.47}$$

In Equation A.47, we used the fact that $C_{ud} = C_{du}$ because the price will be the same in either case.

We know the values of the parameters S and X. If we assume that R, u, and d will remain constant over time, the possible maturity values for the option can be determined exactly. Thus deriving the option's fair value with two periods to maturity is a relatively simple process of working backwards from the possible maturity values.

Using this same procedure of going from a one-period model to a two-period model, we can extend the binomial approach to its more generalized form, with n periods maturity

$$C = \frac{1}{R^n} \sum_{k=0}^{n} \frac{n!}{k!(n-k)!} p^k (1-p)^{n-k}$$
$$Max[0, u^k d^{n-k} S - X] \tag{A.48}$$

To actually get this form of the binomial model, we could extend the two-period model to three periods, then from three periods to four periods, and so on. Equation A.48 would be the result of these efforts. To show how Equation A.48 can be used to assess a call option's value, we modify the example as follows: $S = \$100$, $X = \$100$, $R = 1.07$, $n = 3$, $u = 1.1$ and $d = 0.90$.

First we calculate the value of p from Equation A.42 as 0.85, so $1 - p$ is 0.15. Next we calculate the four possible ending values for the call option after three periods in terms of $Max[0, u^k d^{n-k} S - X]$.

$$C_1 = \left[0, (1.1)^3 (0.90)^0 (100) - 100\right] = 33.10$$

$$C_2 = \left[0, (1.1)^2 (0.90)(100) - 100\right] = 8.90$$

$$C_3 = \left[0, (1.1)(0.90)^2 (100) - 100\right] = 0$$

$$C_4 = \left[0, (1.1)^0 (0.90)^3 (100) - 100\right] = 0$$

Now we insert these numbers (C_1, C_2, C_3, and C_4) into the model and sum the terms.

$$C = \frac{1}{(1.07)^3}\left[\frac{3!}{0!3!}(0.85)^0(0.15)^3 \times 0\right.$$

$$+ \frac{3!}{1!2!}(0.85)^1(0.15)^2 \times 0$$

$$+ \frac{3!}{2!1!}(0.85)^2(0.15)^2 \times 8.90$$

$$\left.+ \frac{3!}{3!0!}(0.85)^3(0.15)^0 \times 33.10\right]$$

$$= \frac{1}{1.225}\left[0 + 0 + \frac{3 \times 2 \times 1}{2 \times 1 \times 1}(0.7225)(0.15)(8.90)\right.$$

$$\left.+ \frac{3 \times 2 \times 1}{3 \times 2 \times 1 \times 1} \times (0.61413)(1)(33.10)\right]$$

$$= \frac{1}{1.225}[(0.32513 \times 8.90) + (0.61413 \times 33.10)]$$

$$= \$18.96$$

As this example suggests, working out a multiple-period problem by hand with this formula can become laborious as the number of periods increases. Fortunately, programming this model into a computer is not too difficult.

Now let's derive a binomial option pricing model in terms of the cumulative binomial density function. As a first step, we can rewrite Equation A.48 as

$$C = S\left[\sum_{k=m}^{n}\frac{n!}{k!(n-K)!}p^k(1-p)^{n-k}\frac{u^k d^{n-k}}{R^n}\right]$$

$$- \frac{X}{R^n}\left[\sum_{k=m}^{n}\frac{n!}{k!(n-k)!}p^k(1-p)^{n-k}\right] \qquad \text{(A.49)}$$

This formula is identical to Equation A.48 except that we have removed the Max operator. In order to remove the Max operator, we need to make $u^k d^{n-k}S - X$ positive, which we can do by changing the counter in the summation from $k = 0$ to $k = m$. What is m? It is the minimum number of upward stock movements necessary for the option to terminate "in the money" (that is, $u^k d^{n-k}S - X > 0$). How can we interpret Equation A.49? Consider the second term in brackets; it is just a cumulative binomial distribution with parameters of n and p. Likewise, via a small algebraic manipulation we can show that the first term in the brackets is also a cumulative binomial distribution. This can be done by defining $P' \equiv (u/R)p$ and $1 - P' \equiv (d/R)(1 - p)$. Thus

$$p^k(1-p)^{n-k}\frac{u^k d^{n-k}}{R^n} = p'^k(1-p')^{n-k}$$

Therefore the first term in brackets is also a cumulative binomial distribution with parameters of n and p'. Using

Equation A.45 in the text, we can write the binomial call option model as

$$C = SB_1(n,\ p',\ m) - \frac{X}{R^n}B_2(n,\ p,\ m) \qquad \text{(A.50)}$$

where

$$B_1(n,\ p',\ m) = \sum_{k=m}^{n}C_k^n p'^k(1-p')^{n-k}$$

$$B_2(n,\ p,\ m) = \sum_{k=m}^{n}C_k^n p^k(1-p)^{n-k}$$

and m is the minimum amount of time the stock has to go up for the investor to finish *in the money* (that is, for the stock price to become larger than the exercise price).

In this appendix, we showed that by employing the definition of a call option and by making some simplifying assumptions, we could use the binomial distribution to find the value of a call option. In the next chapter, we will show how the binomial distribution is related to the normal distribution and how this relationship can be used to derive one of the most famous valuation equations in finance, the Black-Scholes option pricing model.

Example A.1
A Decision Tree Approach to Analyzing Future Stock Price

By making some simplifying assumptions about how a stock's price can change from one period to the next, it is possible to forecast the future price of the stock by means of a decision tree. To illustrate this point, let's consider the following example.

Suppose the price of Company A's stock is currently $100. Now let's assume that from one period to the next, the stock can go up by 17.5% or go down by 15%. In addition, let us assume that there is a 50% chance that the stock will go up and a 50% chance that the stock will go down. It is also assumed that the price movement of a stock (or of the stock market) today is completely independent of its movement in the past; in other words, the price will rise or fall today by a random amount. A sequence of these random increases and decreases is known as a **random walk**.

Given this information, we can lay out the paths that the stock's price may take. Figure A.1 shows the possible stock prices for company A for four periods.

Note that in period 1 there are two possible outcomes: the stock can go up in value by 17.5% to $117.50 or down by 15% to $85.00. In period 2 there are four possible outcomes. If the stock went up in the first period, it can go up again to $138.06 or down in the second period to $99.88. Likewise, if the stock went down in the first period, it can go down again to $72.25 or up in the second period to $99.88. Using the

same argument, we can trace the path of the stock's price for all four periods.

If we are interested in forecasting the stock's price at the end of period 4, we can find the average price of the stock for the 16 possible outcomes that can occur in period 4.

$$\bar{P} = \frac{\sum_{i=1}^{16} P_i}{16} = \frac{190.61 + 137.89 + \cdots + 52.20}{16} = \$105.09$$

We can also find the standard deviation for the stock's return.

$$\sigma_P = \left[\frac{(190.61 - 105.09)^2 + \cdots + (52.20 - 105.09)^2}{16} \right]^{1/2}$$

$$= \$34.39$$

$\bar{P}$ and σ_P can be used to predict the future price of stock A.

Appendix H: Derivation of Modigliani and Miller (M&M) Proposition I and II with Taxes

H.1 M&M Proposition I with Taxes

Assume that the firms are non-growth companies; the market value of levered firm is equal to the market value of unlevered firm plus the present value of the cost of perpetually total debt.

$$V_L = V_U + \sum_{t=1}^{\infty} \frac{TDk_d}{(1+k_d)^t} = V_U + \frac{TDk_d}{k_d}$$
$$= V_U + TD \qquad (A.51)$$

Where V_L = market value of levered firm, V_U = market value of unlevered firm, T = marginal corporate tax rate, D = total debt, k_d = the cost of debt, and TD = tax shield value.

Alternatively, the market value of levered firm, V_L, can be viewed as the total cash flow to all stakeholders

$$(EBIT - k_d D) \times (1-T) + k_d D$$
$$= EBIT \times (1-T) + Tk_d D \qquad (A.52)$$

The cash flow to all stakeholders is made up of cash flow to stockholders plus cash flow to bondholders. The present value of first term is equal to the market value of unlevered firm, V_U, and the present value of second term is TD. Therefore, $V_L = V_U + TD$.

Miller (1977) modified Eq. A.51 by introducing personal as well as corporate taxes into the model, and obtaining

$$V_L = V_U + \left[1 - \left[\frac{(1-T)(1-T^{PS})}{(1-T^{PD})} \right] \right] D \qquad (A.53)$$

Where V_L, V_U, T, and D have been defined in Eq. A.51; T^{PS} and T^{PD} are the personal tax rate on equity income and the personal tax from bond income, respectively. If T^{PS} equals to T^{PD}, then Eq. A.53 can be reduced to M&M Proposition I with taxes.

H.2 M&M Proposition II with Taxes

Since market value of levered firm, V_L, is equal to total equity, E, plus total debt, D, and based on M&M proposition I with taxes, the market value of unlevered firm can be derived as

$$V_L = E + D = V_U + TD => V_U = E + (1-T)D \quad (A.54)$$

The cash flow from each side of balance sheet must equal, therefore

$$Ek_e + Dk_d = V_U k_u + TDk_d$$
$$= (E + (1-T)D)k_u + TDk_d \qquad (A.55)$$

Where E = total equity, D = total debt, k_e = the cost of equity, k_d = the cost of debt, k_u = the cost of unlevered equity, and T = marginal corporate tax rate.

Divide both side by total equity, E, then we can get

$$k_e + \frac{D}{E}k_d = \left(1 + (1-T)\frac{D}{E} \right)k_u + \frac{D}{E}Tk_d$$
$$= k_u + (1-T)\frac{D}{E}k_u + \frac{D}{E}Tk_d \qquad (A.56)$$

$$k_e = k_u + (1-T)\frac{D}{E}k_u + \frac{D}{E}Tk_d - \frac{D}{E}k_d$$
$$= k_u + (1-T)\frac{D}{E}k_u - (1-T)\frac{D}{E}k_d \qquad (A.57)$$
$$= k_u + (k_u - k_d)\frac{D}{E}(1-T)$$

Figure A.2 represents the relationship between the cost of equity with and without taxes, and the cost of unlevered firm. The weighted average cost of capital with taxes will decrease when the ratio of debt to equity increases.

Fig. A.2 The Relationship Between the Cost of Capital and Debt-to-Equity Ratio

Cost of capital (%)

$$k_e = k_u + \frac{D}{E} \times (k_u - k_d)$$

$$k_e = k_u + \frac{D}{E} \times (1 - T) \times (k_u - k_d)$$

k_u

$$WACC = \frac{D}{D+E} \times k_d \times (1-T) + \frac{E}{D+E} \times k_e$$

k_d

Debt-to-equity ratio (D/E)
Appendix I: Derivation of Capital Market Line (CML)

Fig. A.3 The Capital Market Line
By geometric theory, triangles R_fPE and R_fM_pD in the Fig. A.3 above are similar and are, therefore, directly proportional,

$$\Delta PR_fE \cong \Delta M_pR_fD \qquad (A.58)$$

where R_f = the risk-free rate; R_{M_p} = return on market portfolio M_p; R_p = return on the portfolio consisting of combinations of the risk-free asset and portfolio M_p; σ_p and σ_{M_p} = standard deviations of the portfolio and the market; and the operator E denotes expectations.

Therefore,

$$\frac{E(R_p) - R_f}{E(R_{M_p}) - R_f} = \frac{\sigma_p}{\sigma_{M_p}}$$

$$=> \left(E(R_p) - R_f\right) = \frac{\sigma_p}{\sigma_{M_p}}\left(E(R_{M_p}) - R_f\right)$$

$$=> E(R_P) = R_f + \left[E(R_{M_p}) - R_f\right]\frac{\sigma_P}{\sigma_{M_p}} \qquad (A.59)$$

This page intentionally left blank

Appendix J: Derivation of Capital Market Line (SML)
Sharpe (1964) used a general risky asset that did not lie on the CML and dubbed it *I* in Fig. A.4. The combinations of risk and return possible by combining security *I* with the market portfolio, *M*, are shown by figure above. The average return and standard deviation for any *I-M* combination can be approached in the same way as for a two-asset case:

$$E(R_P) = w_i E(R_i) + (1 - w_i)E(R_m) \qquad (A.60)$$

$$\sigma_P = \left[w_i^2 \sigma_i^2 + (1 - w_i)^2 \sigma_m^2 + 2(1 - w_i)w_i \sigma_{im} \right]^{\frac{1}{2}} \qquad (A.61)$$

where w_1 represents excess demand for *I* or demand greater than its equilibrium weight in portfolio *M*, and σ_{im} is the covariance of *i* and *m*.

The change in mean and standard deviation as the proportion w_1 changes are the partial derivatives

$$\frac{\partial E(R_P)}{\partial w_i} = E(R_i) - E(R_m) \qquad (A.62)$$

$$\frac{\partial(\sigma_P)}{\partial w_i} = 1/2 \left[w_i^2 \sigma_i^2 + (1 - w_i)^2 \sigma_m^2 + 2w_i(1 - w_i) \right]^{-\frac{1}{2}}$$
$$\left(2w_i \sigma_i^2 - 2\sigma_m^2 + 2w_i \sigma_m^2 + 2\sigma_{im} - 4w_i \sigma_{im} \right) \qquad (A.63)$$

When $w_i = 0$, the security is held in proportion to its total market value and there is no excess demand for security *I*. This is the key insight to Sharpe's paper, for when $w_i = 0$, it is possible to equate the slope of the curve *IMI'* with the capital market line and thus obtain an expression for the return on any risky security *I*. At equilibrium when $w_i = 0$, the slope along the *IMI'* curve will equal

$$\frac{\partial E(R_P)}{\partial(\sigma_P)} = \frac{\dfrac{\partial E(R_P)}{\partial w_i}}{\dfrac{\partial(\sigma_P)}{\partial w_i}} = \frac{E(R_i) - E(R_m)}{\dfrac{\sigma_{im} - \sigma_m^2}{\sigma_m}} \qquad (A.64)$$

The slope of the capital market line at point *M* is

$$\frac{E(R_m) - R_f}{\sigma_m} \qquad (A.65)$$

Let Eq. A.64 equal to Eq. A.65, then rearranging the terms to solve for $E(R_i)$ gives the equation for the security market line or CAPM

$$E(R_i) = R_f + \left[E(R_m) - R_f \right] \frac{\sigma_{im}}{\sigma_m^2} \qquad (A.66)$$

This represents the return on any risky asset I. At equilibrium, every risky asset will be priced so that it lies along the security market line. It should be noted that the term σ_{im}/σ_m^2 represents the beta coefficient for the regression of R_i vs. R_m, so that Eq. A.66 can be rewritten as

$$E(R_i) = R_f + \left[E(R_m) - R_f\right]\beta_i \qquad (A.67)$$

Appendix K: Derivation of Black-Scholes Option Pricing Model

Assume the stock prices follow a lognormal distribution and denote the current stock price by S and the stock price at the end of t-th period by S_t then $\frac{S_t}{S_{t-1}} = \exp(K_t)$ is a random variable with a lognormal distribution, where K_t is the rate of return in t-th period and follows normal distribution with the constant mean μ and variance σ^2, therefore,

$$E\left[\frac{S_T}{S}\right] = E\left[\frac{S_1}{S}\frac{S_2}{S_1}\cdots\frac{S_T}{S_{T-1}}\right]$$

$$= E\left[\exp(K_1 + K_2 + \ldots + K_T)\right] = T\mu + \frac{T\sigma^2}{2} \quad (A.68)$$

Under the assumption of a risk-neutral investor, the expected return $E\left[\frac{S_T}{S}\right]$ is assumed to be $\exp[rT]$ (where r is the riskless rate of interest). In other words, $\mu = r - \sigma^2/2$.

The call option price C can be determined by discounting the expected value of the terminal option price by the riskless rate of interest (r):

$$C = \exp[-rT]E[Max(S_T - X, 0)] \quad (A.69)$$

where T is the time of expiration and X is the striking price, r is the riskless interest rate, S_T is the stock price at time T. Note that

$$Max(S_T - X, 0) = \left(S\left(\frac{S_T}{S} - \frac{X}{S}\right)\right) \quad \text{for } \frac{S_T}{S} > \frac{X}{S} \quad (A.70)$$

Let $y = \frac{S_T}{S}$ has a lognormal distribution with mean $\mu T = \left(r - \frac{1}{2}\sigma^2\right)T$ and variance $\sigma^2 T$, then

$$C = \exp[-rT]\,E[Max(S_T - X, 0)]$$

$$= \exp[-rT]\int_{\frac{X}{S}}^{\infty} S\left[y - \frac{X}{S}\right]g(y)dy$$

$$= S\exp[-rT]\int_{\frac{X}{S}}^{\infty} yg(y)dy - \exp[-rT]S\frac{X}{S}\int_{\frac{X}{S}}^{\infty} g(y)dy \quad (A.71)$$

Let $x = \ln(y)$, then x follows normal distribution with mean $\mu T = \left(r - \frac{1}{2}\sigma^2\right)T$ and variance $\sigma^2 T$, and

$$dx = \frac{1}{y}dy, \frac{f(x)}{y} = g(y)$$

$$\int_{\frac{X}{S}}^{\infty} g(y)dy = \int_{\ln\left(\frac{X}{S}\right)}^{\infty} \frac{f(x)}{y}(ydx)$$

$$= \int_{\ln\left(\frac{X}{S}\right)}^{\infty} f(x)dx$$

$$= \int_{\frac{\ln\left(\frac{X}{S}\right) - (r - \frac{1}{2}\sigma^2)T}{\sigma\sqrt{T}}}^{\infty} h(z)dz \quad (A.72)$$

Where $g(y)$ is the probability density function of y, $f(x)$ is the probability density function of x, z is standard normal distribution, and $h(z)$ is the probability density function of z. The first term of call option can be derived as

$$
\begin{aligned}
\int_{\frac{X}{S}}^{\infty} e^{-rT} y g(y) dy &= \int_{\ln\left(\frac{X}{S}\right)}^{\infty} e^{-rT} e^{x} \frac{f(x)}{y} (y dx) \\
&= \int_{\ln\left(\frac{X}{S}\right)}^{\infty} e^{-rT} e^{x} f(x) dx \\
&= \int_{\ln\left(\frac{X}{S}\right)}^{\infty} \frac{1}{\sqrt{2\pi\sigma^2 T}} e^{\left(\frac{-\left(x-\left(r-\frac{1}{2}\sigma^2\right)T\right)^2}{2\sigma^2 T} - rT + x \right)} dx \\
&= \int_{\ln\left(\frac{X}{S}\right)}^{\infty} \frac{1}{\sqrt{2\pi\sigma^2 T}} e^{\frac{-\left(x-\left(r+\frac{1}{2}\sigma^2\right)T\right)^2}{2\sigma^2 T}} dx \\
&= \int_{\frac{\ln\left(\frac{X}{S}\right)-\left(r+\frac{1}{2}\sigma^2\right)T}{\sigma\sqrt{T}}}^{\infty} h(z) dz
\end{aligned}
$$

$$(A.73)$$

Where z is standard normal distribution, and $h(z)$ is the probability density function of z. Therefore, the call option pricing model can be rewritten as

$$
\begin{aligned}
C &= S \int_{\frac{\ln\left(\frac{X}{S}\right)-\left(r+\frac{1}{2}\sigma^2\right)T}{\sigma\sqrt{T}}}^{\infty} h(z) dz \\
&\quad - Xe^{-rT} \int_{\frac{\ln\left(\frac{X}{S}\right)-\left(r-\frac{1}{2}\sigma^2\right)T}{\sigma\sqrt{T}}}^{\infty} h(z) dz \\
&= SN(d_1) - Xe^{-rT} N(d_2)
\end{aligned}
$$

$$(A.74)$$

where

$$
d_1 = -\left[\frac{\ln\left(\frac{X}{S}\right)-\left(r+\frac{1}{2}\sigma^2\right)T}{\sigma\sqrt{T}} \right] = \frac{\ln\left(\frac{S}{X}\right)+\left(r+\frac{1}{2}\sigma^2\right)T}{\sigma\sqrt{T}},
$$

$$
d_2 = -\left[\frac{\ln\left(\frac{X}{S}\right)-\left(r-\frac{1}{2}\sigma^2\right)T}{\sigma\sqrt{T}} \right] = \frac{\ln\left(\frac{S}{X}\right)+\left(r-\frac{1}{2}\sigma^2\right)T}{\sigma\sqrt{T}} = d_1 - \sigma\sqrt{T}
$$

Based on put-call parity, it can be shown that the relationship between a call option (C) and a put option (P) can be defined as

$$C + Xe^{-rT} = P + S \qquad (A.75)$$

Substituting Eqs. A.74 into A.75, we obtain the put option formula as

$$P = Xe^{-rT} N(-d_2) - SN(-d_1) \qquad (A.76)$$

where S, C, r, T, d_1 and d_2 are identical to those defined in the call option model.
